Pathology. This has been worked out principally by Mackenzie and Manson, and more recently by Low and Wise. The presence of chyle in the urine is due to the rupture of dilated chyle-containing lymphatic vessels. Owing to some obstruction in the thoracic duct with varicosity of lymphatics below the seat of obstruction, the lymphatics in the bladder walls become dilated and rupture, and so the chyle passes into the bladder.

Low has demonstrated that *lymphuria* takes place when the blockage of the lymphatics is below the thoracic duct and receptaculum chyli. Chemically the only difference between lymph and mesenteric lymph or chyle is that the latter contains a much larger amount of fat, which is derived from the lacteals of the intestine. According to Delamere, the fat contained in lymph does not exceed 5·0 per mille, while in chyle it may be as much as 0·5 per mille.

Symptomatology. The onset of the attack is usually abrupt, without marked symptoms, though vague pains may be felt, and at times there may be fever, pains in back, perineum, and thighs. Usually, however, the patient simply asks advice because he is passing milky or bloody urine.

As a rule the urine clears in the course of time, but it is merely an intermission, and the symptoms will in due course recur, and intermissions and attacks will follow each other for years; on the other hand, however, it may be continuous, and not intermittent. The duration of the intermissions may be days, months, or years, while the attacks may be attributed to exertion or emotion. After continuing for some time it may lead to exhaustion, neuralgic pains in different parts of the body, disordered bowels, coated tongue, dry, harsh skin, and a state of cachexia.

If the urine clots in the bladder, there may be severe pain and strangury. The urine generally presents the appearance of milk, but may be pinkish in colour from admixture with blood, and a large portion may clot into a semitransparent gelatinous mass. It is usually passed in fair quantity, and it will be noticed that the morning urine is usually very clear, while that at night is much more milky or red. On standing, in true chyluria, the fat accumulates on the surface, giving rise to a cream-like appearance. Under the microscope, as a rule no fatty globules, however minute, are observed, but white corpuscles, especially lymphocytes, and red corpuscles, and at times *Microfilariæ* and crystals of calcium oxalate, may be seen. The specific gravity is low, varying from 1015 to 1020. The reaction is usually acid. On shaking the urine with ether, the fat can be removed and estimated, when it will be found to vary from 0·8 to 1·8 per cent. After the removal of the fat, the urine can be tested for albumen, which is always present, and which usually persists for some time after the fat has disappeared. The quantity of albumen varies from 0·6 to 0·9 per cent. Albumoses and sugars are absent.

When the urine does not contain any distinct amount of fat one speaks of lymphuria, and if blood is present hæmato-lymphuria. The same patient may have at times attacks of chyluria and hæmatochyluria, and at other times attacks of lymphuria and hæmatolymphuria.

Treatment.—The treatment is purely symptomatic, and consists of rest in bed, lying as much as possible in the prone position, while in some cases methylene blue may be given in 2-grain doses, together with salol, 5 grains, or urotropine in 5-grain cachets. The diet must be bland, non-irritating. Astringent injections into the bladder have been used, and gallic acid, nitrate of silver, acetate of lead, iodide of potassium, and thymol have been administered internally, but have not been found to be efficacious. Indeed, there is no justification for their use. Administration of quinine, combined with exposure to X rays, has been recommended by Musgrave and McDill.

If the urine clots in the bladder, it must be washed out under chloroform by means of an aspirator, and if this is not successful, the bladder may have to be opened and drained.

Chylous and Lymph Diarrhœa.

Diarrhœa with chyle or lymph and blood in the motions has been recorded, but is rare.

Chylocele or Lymphocele.

This may develop gradually, the tunica vaginalis filling up with an opaque fluid, which on tapping is found to be chylous, and may contain *Microfilariæ*. It may, however, be preceded by an attack of fever and orchitis. It is said that the sac is less tense in the morning, and more so at night.

Treatment. A chylocele does not grow to any large size, and only requires occasional tapping.

Chylous Ascites.

Chylous ascites is rarely met with in human beings, though we have seen two cases. It is common in animals as the result of filarial infection.

ELEPHANTIASIS.

Synonyms. Elephant Leg, Cochin Leg, Barbados Leg, Galle Leg, Glandular Disease of Barbados, Elephantiasis Arabum, Da-Fil, Dau-ool-Fil, Pes Febricitans, Perical, Phlegmasia Malabarica, Elephantiasis Indica, Bucnemia Tropica, Morbus Elephas, Spargosis Fibroareolaris, Pachydermia, Hernia Carnosa, Elephantiasis Tuberosa et Scrotalis, Hypersarcosis, Mal de Cayenne, Sarcocèle d'Egypte, Roosbeen von Surinam. Shlipada, Kosharriddki, Barawa (Sinhalese).

Definition.—Elephantiasis is a chronic inflammatory hypertrophy of the fibrous connective tissue of a region of the body induced by lymph stasis, and resulting in a considerable hypertrophy of the skin and subcutaneous tissues.

Varieties.—The most common varieties of elephantiasis are the affection of the leg, scrotum, vulva, arm, and breast, while other regions are much more rarely affected. The different varieties must now be briefly described.

Elephantiasis of the Leg.

Symptomatology.—During attacks of filarial lymphangitis of the leg it is noticed that the limb becomes swollen, and though after the first attack it may resume its normal size, this does not happen after repeated successive attacks, and gradually the limb becomes

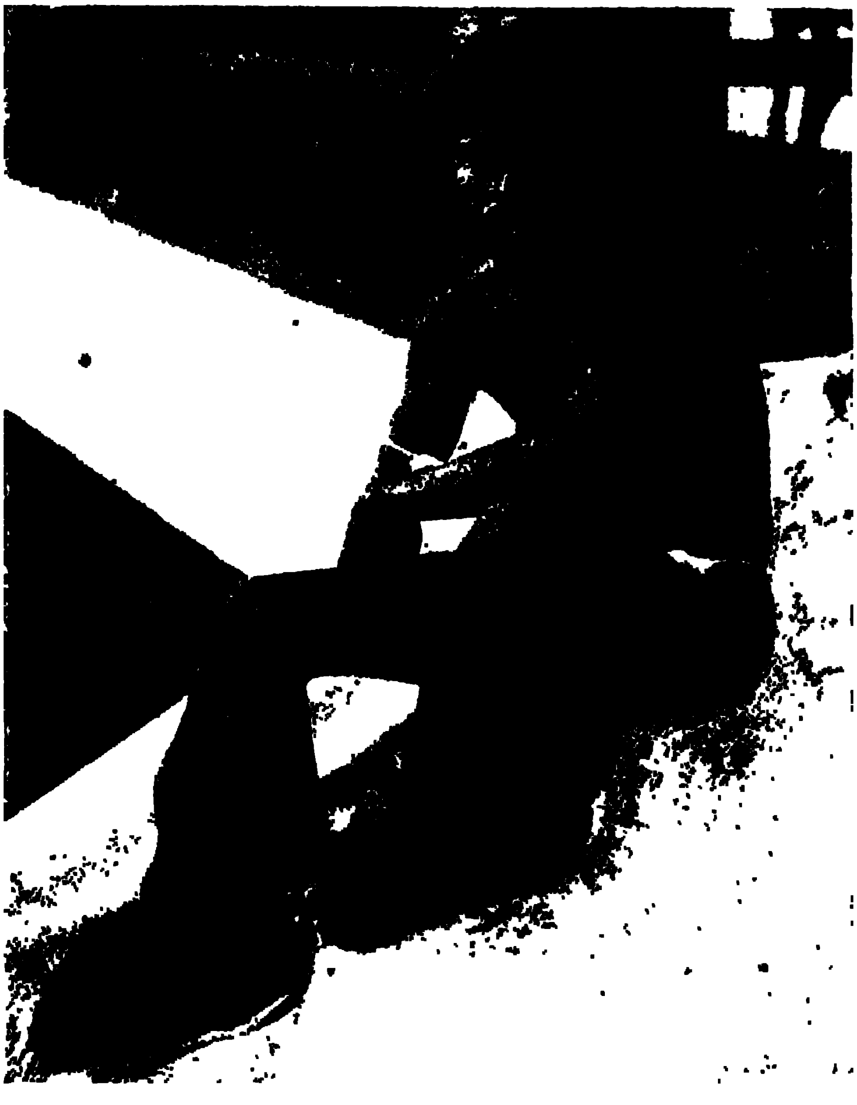

FIG. 718.—ELEPHANTIASIS OF THE LEGS.

more and more swollen, while the natural folds, especially the ankle fold, become much exaggerated by the swelling on either side, so that deep sulci are formed. The dorsum of the foot becomes swollen and puffy, and is separated by the deep ankle sulcus from the swollen lower part of the leg. In these sulci the débris of the cast-off epithelium, together with the excretions of the skin, accumulate and give rise to a foul smelling discharge, and ulcers may form. At first the skin is smooth and soft, forming the smooth variety of the complaint, which may persist, or it may become dark, hard, thick, and rough, being elevated into bosses or warty elevations, forming the verrucose variety. The appendages now atrophy from malnutrition, the hairs may drop off, and the nails become rough and thickened, while the skin perspires less and the sensibility is diminished. Ulcers may now form on almost any part of the foot. The swelling is more commonly met with below the knee, but the whole thigh may become implicated.

ELEPHANTIASIS OF THE LEGS.

If left untreated, the size of the leg gradually increases with repeated attacks of fever, and may reach considerable dimensions.

After some years the attacks of fever may cease altogether, though the condition of the leg usually remains unchanged. In some rare cases elephantiasis may develop without the patient ever having an attack of fever.

Treatment. —A radical method of treatment has yet to be found. Of the various palliative ones the most satisfactory is perhaps that introduced by Castellani, which consists in keeping the patient at complete rest in bed, with thiosinamin or fibrolysin injections and methodical bandaging. The details of the treatment are as follows: The patient is kept in bed and an injection of 2 to 4 c.c. of fibrolysin Merk (which consists of thiosinamin and salicylic acid dissolved in water) is given daily for three to six months, the injections being interrupted for a few days from time to time. The injections may be made in the affected parts, or deeply into the gluteal region, where they cause much less pain. After each injection the whole limb is tightly bandaged with flannel bandages, which are kept in place day and night. In some cases rubber bandages may be used with great advantage, especially in cases of verrucose elephantiasis, because they render the skin much smoother. Unfortunately, many patients cannot stand rubber bandaging. To increase the pressure on the hardest parts pads of inelastic material may be applied before bandaging, and for this purpose small cylindrical

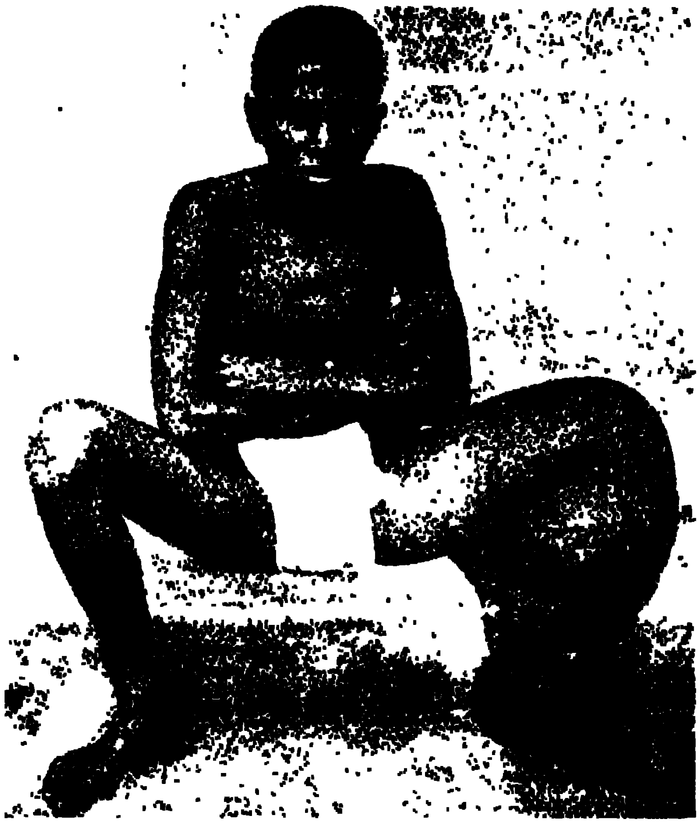

FIG. 720.—ELEPHANTIASIS OF THE LEG: BEFORE TREATMENT.

gauze bags filled with ordinary small lead shot are found especially useful. In some cases massage of the whole limb before bandaging is useful. It is of the utmost importance that the pressure on the whole limb should be well distributed, otherwise the parts on which insufficient pressure has been made will be found to become swollen. It is also useful to keep the affected limb continually elevated by means of pillows, etc. In cases of verrucose elephantiasis in which the skin is covered with numerous horny masses, a spirit lotion of resorcin and salicylic acid (ac. salicylici, resorcin, āā gr. xxx.; sp. rect., ℥iv.) is useful in removing these horny masses.

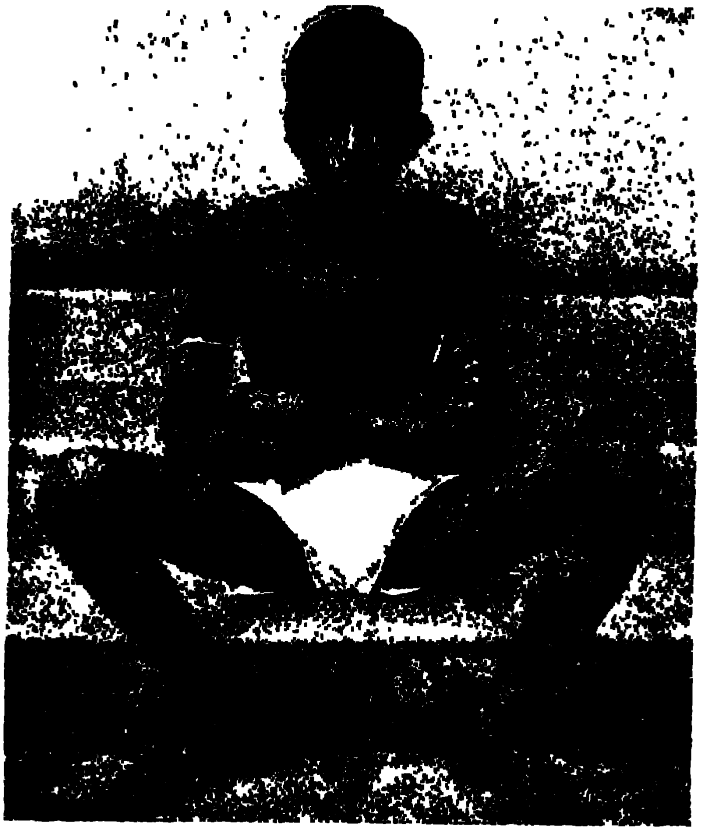

FIG. 721.—THE SAME CASE AS IN FIG. 720: AFTER TREATMENT BY FIBROLYSIN AND BANDAGING, AND WITHOUT ANY OPERATIVE MEASURES.

In successful cases after three to six months of this treatment the affected parts are of much smaller size, the skin is smoother, more elastic, and can be pinched into folds. Long elliptical strips of the redundant skin and subcutaneous tissue may then be removed, the margins of the wound being stitched together. This would not be practicable before the medical treatment, as the skin being enormously thickened and inelastic, the coaptation of the opposed surfaces could not be obtained.

In our experience this treatment has generally only a slight and temporary effect in recent cases when the disease is in the acute stage with frequent attacks of filarial fever. On the other hand, the treatment gives much better and more lasting results in old-standing cases, especially in those of the verrucose type, characterized by the enormous new formation of fibrous tissue and absence of fever. After treatment the patient should wear puttees or elastic stockings, and the rubber bandage should be applied from time to time.

Handley has treated cases by first preparing a vaccine from the diplococcus which he found in the blood, and administering this until the blood and lymph become sterile, and then performing his operation of 'lymphangioplasty,' by silk introduced by means of long probes, which are pushed along the subcutaneous tissues, through small incisions, until a path is made from the affected region to one with a normal lymph circulation. In the cases so far reported there was marked improvement at first after operation, but this did not last long. Madden and Ferguson report unfavourably on lymphangioplasty as a treatment for elephantiasis of the legs, as they find the temporary improvement not maintained, because the reactive changes in the tissues immediately around the thread eventually obliterate the new vessels. Sistrunk reports favourably on the Kondoléon Operation, the aim of which is to establish by a wide excision of the aponeurosis, a communication between the superficial and deep lymphatic channels.

Other methods of treatment consist in bandaging, massage, tapping with Southey tubes, and even amputation, but none of these are satisfactory.

Elephantiasis of the Scrotum.

The disease may begin as a lymph scrotum, or with recurring erysipelatous attacks, with a red inflammatory blush on the skin, and fever. After each attack the scrotum is larger than it was before, and it goes on growing, if left alone, until it may reach the weight of 224 pounds, as mentioned by Chevers, which is probably the largest ever described. When well developed it forms a triangular-shaped mass hanging down between the legs, with the base downwards, and the apex upwards towards the pubes. On its anterior and upper aspect there is an aperture which leads into a canal, formed by the inverted prepuce, at the bottom of which is the glans penis. The penis itself is buried in the tumour. The testicles are situated at the upper and back part of the tumour, and are usually surrounded by hydroceles.

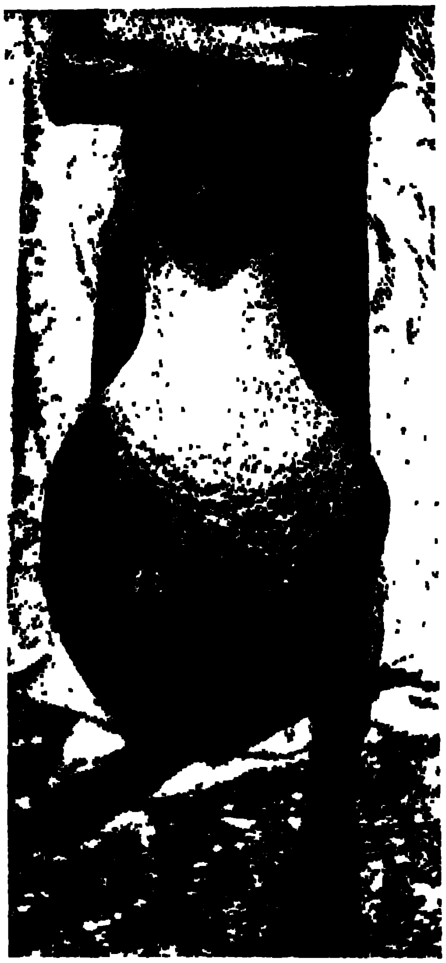

Fig. 722.—Elephantiasis the Scrotum.

If large, the base of the tumour is frequently ulcerated.

Treatment.—The treatment is removal, which is a very easy operation, and very successful, following either Manson's or Charles's method. Manson says that the mortality need not exceed 5 per cent.

The most important feature of the whole operation is to have the skin perfectly clean and aseptic, and to carefully choose the parts of the skin which are to be used as flaps.

An elastic tourniquet in a figure of eight is applied round the pelvis and the neck of the tumour. The skin flaps are now marked out and deepened, the vessels being carefully ligatured as they are exposed.

The testicles are then dissected by perpendicular cuts, and the penis is set free by dissection, after cutting down the canal already mentioned as formed by the prepuce. This is best done with a pair of scissors.

The general mass of elephantoid tissue is now cut away, gradually ligaturing the vessels as the cutting process goes on, this preventing any of the vessels being passed over. The tourniquet is now loosened, and any bleeding spot secured.

If there are hydroceles present, these are opened, and the sac turned inside out, and after any redundancy has been removed, it is stitched around the testicle in the inverted condition. The flaps are now brought together and stitched over the testes, a drain of some description being introduced at the lower portion of the wound if this is considered to be necessary. Skin flaps should, if possible, be made for the penis: failing this, the raw area must be covered with protective, and allowed to granulate. The whole wound must now be antiseptically dressed, and usually heals without difficulty.

Sir Havelock Charles' Operative Method.—After the usual preparation an incision is made in the median line from near the pubis to the preputial mouth deepening it to the dorsum of the penis. Enucleation of the organ is performed from the suspensory ligament to its free extremity. There the glans is still separated from the finger by the lining membrane of the prepuce. The head of the penis is pulled up and this cap of mucous membrane is cut through in front of the glans, which is easily palpable through it. The organ is now free, with its head, covered with a sort of cap, which is next slit up, and the parts thoroughly cleaned. Now the mass is pulled to the patient's right, exposing the left side of the neck of the tumour. Cut from above, near external abdominal ring, curving towards the median line in front of the anus. Deepen this incision gradually with finger and scalpel to near the bulb, avoiding hurting it. The trunks of the vessels can be seized with pressure-forceps before section or after cutting. The same procedure is repeated on the right side of the neck of the tumour. The two incisions will meet in front of the anus, all the main vessels will be seized and divided, and the bulb almost cleared on both sides.

Then the testicles are enucleated, and after wrapping them, as well as the cords, in gauze, they are placed on the pubis. The flaps are now made, practice determining the amount of covering necessary. Place the right testicle under the skin flap on the thigh. Repeat the same with the left testicle and draw the flaps to the median line. A few temporary stitches to keep them in position, whilst a continuous suture run quickly up holds them firmly. Lastly flaps are stitched to the body of the penis.

After the operation careful dressing, well and equally applied, is of great practical importance.

Elephantiasis of the Vulva.

This arises in the same manner as elephantiasis of the scrotum, and may affect the labia majora or the clitoris. It is, however, very rare. The tumour, according to Manson, may weigh 8 to 10 pounds, or more. The treatment is removal.

Elephantiasis of the Breast.

Elephantiasis of the breast is very rare, but does occur, and the enlarged breast may reach to the pubes or the knee. It may affect one or both breasts. The treatment is removal.

Elephantiasis of the Arm.

This is rare, but may arise in the same manner as in the leg. One arm or both arms may be affected. Bahr reports that the natives of Fiji and probably of other South Pacific Islands are, in comparison with natives of other regions, peculiarly liable to this form of elephantiasis.

Elephantiasis of the Scalp.

Rarely the whole scalp is enormously thickened, and presents deep furrows.

Circumscribed Elephantiasis.

Large pendulous tumours of filarial origin, one to several, may be found. These are commonest in the upper part of the thigh, just below the groin.

RARER AFFECTIONS.

Lewis has recorded a case of filariasis in which chyle containing *Microfilariæ* was discharged from both conjunctivæ, while Maitland has described cases of acute synovitis of the knee associated with filariasis as being of too frequent occurrence to be looked upon as merely coincidences.

FILARIASIS CAUSED BY OTHER FILARIIDÆ.

The lesions produced by *Dracunculus medinensis* (Linnæus, 1758), *Loa loa* (Guyot, 1778), *Onchocerca volvulus* (Leuckart, 1893), and other filarial worms, are described in Chapters LXXXVII., p. 1964, and LXXXVIII., p. 1968, while the zoological account of these worms can be found in Chapter XXVI., p. 621. It will be remembered that *Filaria immitis* Leidy, 1856, found in the dog, does not occur in man, the supposed case being wrongly quoted.

CHAPTER LXVII

THE MYIASES AND ALLIED CONDITIONS

The Myiases: Rhinal; Aural; Ocular; Urinary; Vaginal; Oro-gastro-intestinal; Dermal—Allied conditions—References.

THE MYIASES.

Definition.—The myiases are the invasions of any part of the body of man or animals by dipterous larvæ.

Nomenclature.—In 1815 Kirby and Spence suggested the name 'scholechiasis' for the infestations of man and animals by insects and their larvæ. In 1840 Hope proposed a series of terms applying to various groups of insects, some of which have come into general use, and all of which are employed in this chapter. Thus he names the invasion of dipterous larvæ 'myiasis,' while that due to the larvæ of lepidoptera he calls 'scolechiasis,' and that brought about by beetles 'canthariasis.' In the present chapter we utilize all these old terms and keep the names 'diplopodiasis' and 'chilopodiasis,' which we have already used in previous editions, while we increase the number by turning one of Hope's terms into 'dermapteriasis.' Some of these old terms may not appear very suitable, but they are the first to be suggested.

Historical.—The history of the myiases may be divided into 'ancient knowledge' and 'modern knowledge.'

Ancient Knowledge.—As the disease is much more frequently found in animals than in man, it is not surprising to find that it was first recorded in them. According to Sambon, it was well known in animals to the Babylonians, and to the Ancient Egyptians, Greeks, and Romans. According to the same authority, it was recognized in man even in the Middle Ages. In the tenth century there appeared a book entitled 'The Leech Book' of Bald, or *Medicinale Anglicum*, which described the 'ana-worm' as growing in man and eating through to the outside and shedding itself out of the hole so made. Sambon says this may well have been the larva of *Hypoderma bovis*. In the eleventh and twelfth centuries the Arabian physicians mention a malady called 'bovine disease,' which may have been an infestation with the larva of the same fly. In the sixteenth century Ambrose Paré gave an account of several infestations by larvæ, and illustrated the paragraphs with fanciful drawings of maggots.

In 1589 Father Pedro Simon wrote an account of the occurrence of the fly which we now call *Dermatobia hominis*, as seen along the banks of the Rio Magdalena and in the low plains to the east of the Andes. This appears to be the first reference to the subject as seen in the tropics.

These observations were extended in 1653 by Father Bernabé

Cobo, who states that in each wound caused by the common mosquito there grows a *spine-covered worm* the size of a haricot bean or larger.

About this time Fernelius described some form of nasal infestation—perhaps a myiasis—as occurring in soldiers.

In 1687 Leuwenhoek, in Europe, mentions two cases, one of dermal myiasis in the leg of a woman who made a good recovery, and another in the mouth of a second woman, who died. The larvæ are thought by Hope to belong to the Muscidæ.

Modern Knowledge.—With the appearance of the work of Antonio Vallisneri in the early years of the eighteenth century, a much better conception of these infestations of animals and man became possible, and from this time onwards the knowledge of the subject increased and improved. In 1745 there appeared a work entitled 'Relation abrégée d'un voyage fait dans l'intérieur de l'Amerique Méridionale,' by De la Condamine, where, on p. 170, he mentions the 'ver macaque'—*i.e.*, the larva of *Dermatobia hominis* (Linnæus junior), and says that it takes its birth in the wounds made by a kind of mosquito, but from whence its egg comes is unknown. This observation has since been fully confirmed by recent research. In 1757 Arture drew attention to the occurrence of *Dermatobia hominis* in Cayenne, and in 1781 Linnæus junior did the same as regards Peru in a letter addressed to Pallas, in which he gave the fly its present name. Gmelin subsequently published this letter.

Somewhere about this time Turner described two cases of urinary myiasis in England.

In 1770 Wohlfart published an account of rhinal myiasis in his work entitled 'De Vermibus per nares excretis.'

In 1809 Azara gave a history of his journey in 1781-1801 into Paraguay, and wrote an account of a rhinal myiasis, most probably due to the larvæ of the fly we now call *Chrysomyia macellaria.*

About the same time Lemprière described the same condition in Jamaica, where it caused the death of a woman, and Sells gave an account of probably the same larva causing infestations of the eyes, ears, nose, and mouth in the same islands. Some of Sells's cases ended in recovery and others in death. Also about the same time (1806) comes the case of the soldier believed to be infested with *Œstrus hominis* Curtis in the skin near the scapula in Surinam.

In 1817 Schock studied gastro-intestinal myiasis.

In 1830 a sailor in Demerara is noted to be suffering from myiasis in the arm. This was thought to be caused by a species of Œstrus. In 1832 Howship recorded *Œstrus hominis* in the scrotum of a carpenter in Colombia; in 1835 Guyon mentioned a dermal myiasis in a negro in Martinique; in 1837 Hope described *Dermatobia hominis* in the head of a man, and called it *Œstrus guildingii*, after L. Guilding of Trinidad, who found the case.

In 1840 there appeared the classical and much neglected work on the whole subject by Hope, in which not merely are the older accounts gathered together, but also clear definitions of the various conditions are provided.

From this time onwards the observations on myiasis increase in number—*e.g.*, Duncan in 1854, while in 1856 Lahory described 'peenash,' an East Indian name for an infection due to the larvæ of sarcophaga, while in 1879 Portschinsky again drew attention to gastro-intestinal myiasis. From 1890 to 1896 there appeared a series of classical works by R. Blanchard on myiasis in general. From 1895 to the present time Austen has contributed many valuable articles dealing with these infestations. In 1903 Ward gave an excellent and well-illustrated account of the larva of *Dermatobia hominis*, Kayser in 1905 of ocular myiasis, Henneberg in 1903 and Vesescu in 1906 of aural myiasis, the Sergents in 1907 of thim'ni, and in 1908 Austen and Smith gave accounts of infestation with *Cordylobia anthropophaga*. In 1913 Rodhain, Pons, and others, studied the method of infection by this maggot. Finally, in 1915, Sambon gave an interesting account of *Dermatobia hominis* and its larva.

The above history is sufficient to indicate the large amount of scattered literature in existence dealing with the subject of myiasis in one or more of its phases, and of which Peiper's book, published in 1900, gives a summary.

Ætiology.—At the present moment too little is known as to the characters of the larvæ of the diptera to permit their recognition, unless belonging to a well-known species, and it is obviously incorrect to assume that larvæ are those of a given fly. It is therefore necessary for the medical observer to:—

1. Preserve specimens of the larvæ, as little damaged as possible, in 4 per cent. formalin, and held in position in the tube by means of fine tissue-paper.
2. Rear the larvæ or pupæ and so obtain the imago, which should be fed for a day or so before being killed, and should then be carefully mounted and preserved. Mr. Austen has asked that some of the larvæ should be placed at once on the top of a pot of fairly dry earth, which is then covered with muslin. After the flies have appeared they should be allowed to remain undisturbed for about twenty-four hours in order that they may dry themselves, and in order that they may develop their specific colours, after which they may be killed with chloroform, screwed up in cigarette-paper, packed in small metal boxes, and forwarded to England for identification.
3. Label all the specimens, especially noting the part of the body infected, the locality of infection, and the time of the year.
4. Send the complete collection to the British Museum, Natural History Section, Cromwell Road, London, S.W.

If this is done systematically it will be possible to obtain a correct diagnosis as to the fly causing the myiasis.

The lists of flies known to cause the various forms of myiasis will be given under the different diseases, but it may be noted that the principal families concerned are:—

1. *Muscidæ* (Subfamily: Muscinæ).—Genera: Musca, Calliphora, Chrysomyia, Cordylobia, and Lucilia.

2. *Sarcophagidæ.*—Genera: Sarcophaga, Sarcophila, and Cynomyia.

3. *Anthomyidæ.*—Genus: Fannia.

4. *Œstridæ.*—Genera: Hypoderma, Gastrophilus, Œstrus (Cephalomyia), Œstromyia, Spilogaster. For zoological details on flies see Chapter XXXIII., p. 814.

Less important families are:—*Tachinidæ, Micropezidæ, Syrphidæ, Phoridæ, Therevidæ, Sepsidæ,* and *Drosophilidæ.*

The larvæ appear to be attracted by fæcal or urinary substances, and also by any purulent or putrefactive discharges.

Pathology.—The changes produced in the body by these larvæ appear to depend upon the question of food. In such positions as the alimentary tract they appear to do little harm, probably because there is plenty of food available without hurting the tissues of the host; on the other hand, in the nose, ear, and eye they may cause much destruction of tissue, firstly by eating into the tissues, secondly by the microbic infections which follow in their track, and in this way they may cause the death of the host.

Symptomatology.—As may be expected from the last paragraph, the symptoms of the victim may vary from nil, local signs of destruction of tissue, with inflammation and pus formation, to signs of general septicæmia.

Diagnosis.—This is usually easy, and depends upon the discovery of the larvæ, which, indeed, are usually sufficiently obvious to the patient and practitioner alike.

Treatment.—When the larvæ live in passages such as the nose or ear it is usual to expel them by douches of chloroform water; when in the alimentary canal, by anthelmintic treatment: when in the skin, by the knife and forceps, or simply by the latter. The associated inflammation as well as the conditions causing the original stinking discharge which attracted the flies require treatment, otherwise the patient will again be in danger of infection.

Prophylaxis.—Any person suffering from a purulent or odoriferous discharge in any part of the body should be especially careful to avoid myiasis by sleeping under mosquito curtains until this disease is cured. Other people should be careful not to sleep in the open without some protection, especially in the daytime, and in certain cases—as, for example, *Dermatobia cyaniventris*—to use mosquito curtains.

Varieties.—The various forms of myiasis may be classified as follows:—

A. *Internal or Cavity Myiases* :—

I. Rhinal myiasis.
II. Aural myiasis.
III. Ocular myiasis.
IV. Urinary myiasis.
V. Vaginal myiasis.
VI. Gastro-intestinal myiasis.

B. ***External or Dermal Myiases*** :—

VII. Traumatic dermal myiasis.
VIII. Subcutaneous myiasis.

With regard to the ocular myiases, they may be a true cavity myiases if the larva lives in the lachrymal sac, but they may resemble a cutaneous myiasis if the larva penetrates into the tissues under the conjunctiva, when, indeed, it may destroy the eye.

THE INTERNAL OR CAVITY MYIASES.

RHINAL MYIASIS.

For purposes of description this may be divided into the American rhinal myiasis, the African rhinal myiases, the Asian rhinal myiases, and the European nasal myiases.

American Rhinal Myiasis.

BICHEIRO.

Definition.—Bicheiro is a rhinal myiasis found in Tropical America, and caused by the larvæ of *Chrysomyia macellaria* (Fabricius, 1794) and allied species.

Climatology.—The causal fly extends really from Canada to Patagonia, but is so much more common in the tropical regions as to justify the definition. In Canada it is diminished in numbers by the cold of the winters. In the Southern United States it is met with principally in the months of July to October.

Ætiology.—*Chrysomyia macellaria* (p. 847) usually deposits its eggs in some wound in cattle—*e.g.*, in the wounds after castration, spaying, branding, dehorning, in barbed-wire wounds, and where ticks have been burst or in the vulva, especially if there is a retained placenta, or in the navel or mouth of young calves. More rarely they lay eggs in the wounds of horses and mules produced by barbed wire, in the sheaths of horses, the vaginæ of mares, and the navels of colts. Hogs are also liable to be infested, but sheep are rarely attacked unless they have been worried by dogs.

In place of these more natural hosts the fly may at times attack man, probably being attracted by the odour of what to the human being is an offensive breath, or by an ozæna, or even a chronic catarrh. The fly then passes into one nostril, and if it is expelled dashes into the other nostril, and quickly deposits its eggs, sometimes in large numbers.

In Trinidad, Lawrence reports that the disease may be caused by *Chrysomyia viridula* Robineau-Desvoidy.

Pathology.—The eggs deposited in the manner just described become larvæ in the course of a couple of days. The larvæ proceed to feed upon the tissues of the nose and to burrow deeply into this mucous membrane, down to and even through the bone. The feeding excites a violent reaction on the part of the body, which can be exemplified by the fever, the discharge, the pains, etc.

Morbid Anatomy.—The morbid anatomy includes the destruction of the nose, pharynx, hard and soft palates, larynx, etc. Fistulous channels may be seen packed with larvæ and extending in all directions.

Symptomatology.—Some couple of days after a person suffering from a chronic catarrh, foul breath, or ozæna, has slept in the open, or has been attacked by a fly when riding or driving—*i.e.*, when the hands are engaged—signs of a severe catarrh appear, accompanied with inordinate sneezing and severe pain over the root of the nose or the frontal bone. Quickly the nose becomes swollen, and later the face also may swell, while examination of the nose may show the presence of the larvæ. Left untreated, the patient rapidly becomes worse, and pus and blood are discharged from the nose, from which an offensive odour issues. Cough appears as well as fever, and often some delirium. If the patient lives long enough, the septum of the nose may fall in, the soft and hard palates may be pierced, the wall of the pharynx may be eaten away, exposing the vertebræ, and even the hyoid bone may be destroyed. By this time, however, the course of the disease will have become quite evident by the larvæ dropping out of the nose, and if the patient continues to live all the larvæ may come away naturally.

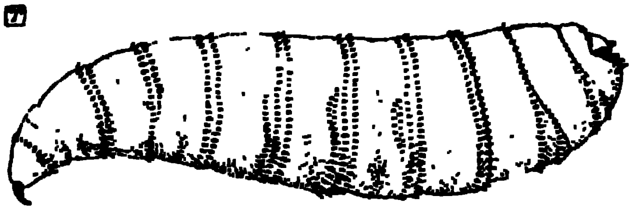

FIG —*Chrysomyia macellaria*: LARVA. (×4.) (After Blanchard.)

Diagnosis.—Any case with the history of a fly having darted into the nose should be assumed to be a case of nasal myiasis until proved by careful nasal examination not to be so. The onset of peculiar sensations at the root of the nose and along the orbital processes, together with the signs of an aggravated nasal catarrh occurring in the endemic region especially in the months of July to October, when the fly abounds in the Southern United States, makes the diagnosis probable, and this becomes a certainty on finding a larva by examination or douching. The onset of the severe symptoms will clear the diagnosis if not evident at an earlier stage.

Prognosis.—The prognosis is always serious, as it is difficult to be sure that all the larvæ have been removed.

Treatment.—The best treatment is to douche out the nose with chloroform water or a solution of chloroform in sweet milk (10 to 20 per cent.), and to follow this with douches of mild antiseptics.

Calomel may be insufflated after douching. It may be necessary to open the frontal or other sinuses, and to irrigate the passages.

Prophylaxis.—The prophylaxis consists in the avoidance of sleeping in the open air except under a mosquito curtain, and in the prompt treatment of any case in which a fly has been known to enter the nose.

The African Rhinal Myiasis.

THIM'NI.

Synonym.—Tamné (Ahaggar Mountains).

Definition.—Thim'ni is a facial myiasis—that is to say, an ocular, rhinal, and oral myiasis—found in certain parts of Algeria and the Ahaggar Mountains of Central Sahara, where the human population is relatively great and the numbers of sheep relatively small. It is caused by the larvæ of *Œstrus* (*Cephalomyia*) *ovis* Linnæus, 1761.

Historical.—In 1881 Kirschmann in Russia reported a case of myiasis due to *Œstrus ovis*, but was disbelieved. In 1907 the Sergents drew attention to the disease thim'ni, and in 1913 to tamné.

Climatology.—It occurs in Algeria, but not everywhere, being confined to certain mountainous regions where the ovine population is relatively little numerous as compared with the human population, and the fly is compelled to find new abodes for its larvæ. These regions are, La Grande Kabylie, La Petite Kabylie, and Le Dahra Oriental. It also occurs in the Ahaggar Mountains of the Central Sahara.

Ætiology.—*Œstrus ovis* (pp. 826, 827) should lay its eggs in the nasal cavities of sheep, and is only driven by force of circumstances to occasionally attack man. It only infests the shepherds and their dogs, being, it is thought, attracted by the cheese which both eat. It appears in the hottest part of the day in the warm weather, and, flying swiftly, deposits its egg, while still on the wing, into the nose, on to the conjunctiva or lips. The larva enters these cavities and causes much pain and inflammation.

Symptomatology.—In the nose it causes severe pain and inflammatory swelling of the whole organ. Frontal headache is intense, sleep is impossible, while a serous discharge runs away from the nose. In the eye vision is impossible, the eyelids and conjunctivæ swell, and little worms are seen on their surface. In the mouth there is much inflammation of the throat, which renders swallowing a difficult proceeding.

The duration is from three to ten days, being longest in the nose.

Prognosis.—This is quite good, as all cases recover.

Treatment.—The essential treatment is tobacco, as smoke or as injections or washes, but in the eye gentle removal is all that is required.

OTHER AFRICAN RHINAL MYIASES.

In addition to thim'ni, rhinal myiasis in Africa is known to be due to:—*Lucilia hominivorax* (*vide* Bouchet at Barika in 1895);

Sarcophaga nura Rudolphi, by Mouchet at Katanga; *Pycnosoma putorum* Wiedemann, 1830, in Abyssinia, Belgian Congo, and Lorenzo Marques. The condition has been reproduced experimentally in animals by Wellman, in 1906, with *S. regularis* Wiedemann in a goat.

Asian Rhinal Myiases.

PEENASH.

Definition.—Peenash is a word which may be used for the Indian rhinal myiases caused by the larvæ of species of *Pycnosoma* Brauer and von Bergenstamm, and by larvæ of species of *Sarcophaga* Meigen, especially by those of *Sarcophaga carnaria* Linnæus, 1758.

Climatology.—The disease is spread throughout India and Assam.

Symptomatology.—As far as is known, the symptoms resemble those produced by other forms of rhinal myiasis.

Treatment.—This is the same as for other forms (*vide supra*).

European Rhinal Myiases.

These are known to be caused by *Piophila casei* and by species of *Sarcophaga* Meigen, 1826, while *Calliphora limea* is also said to be causal.

AURAL MYIASIS.

Definition.—Aural myiasis is the invasion of the external auditory meatus, the middle ear, and associated cavities, by the larvæ of certain dipterous flies, especially those of the Muscidæ and Sarcophagidæ.

Historical.—Aural myiases have been recorded by Taschenberg in 1870, Blake in 1872, Johnson in 1892, and Austen in 1912, but the most complete study is that by Francaviglia in 1914.

Ætiology.—The following larvæ have been noted as causal agents:—

Muscidæ (Subfamily: Muscinæ):—
- *Musca domestica* Linnæus.
- *Musca vomitoria* Linnæus, 1758.
- *Calliphora erythrocephala* Meigen.
- *Chrysomyia macellaria* Fabricius, 1794.
- *Lucilia cæsar* Linnæus.
- *Lucilia nobilis* Meigen.

Sarcophagidæ :—
- *Sarcophaga carnaria* Linnæus, 1758; synonym, *S. carnosa* L., 1758.
- *Sarcophaga magnifica* Schiner, 1862; synonyms, *S. wohlfarti* Portschinsky, 1875, *S. ruralis* Meigen, *S. meigeni* Portschinsky.

Anthomyidæ :—
Fannia scalaris Meigen.
Fannia canicularis Linnæus.
Fannia incisurata Zett.
Hydrotæa meteorica Linnæus.

Syrphidæ :—
Syrphus, sp.??

Œstridæ :—
Œstrus ovis Linnæus, 1761.

Symptomatology.—If lodged in the external auditory meatus, they may simply cause deafness and ringing in the ears, but if eating into the middle ear they may give rise to a discharge of blood and pus.

Treatment.—It is usual to drop into the ear warm olive or carbolic oil, and then to syringe out the larvæ by means of boric lotion. If the larvæ are outside the tympanum, inject a few drops of chloroform dissolved in water.

Prophylaxis.—Some protection such as wool is necessary when suffering from an aural discharge.

OCULAR MYIASIS.

Definition.—Ocular myiasis is the invasion of the spaces under the eyelids, the lachrymal sac, the subconjunctival tissue, or the eyeball itself, by dipterous larvæ usually belonging to the families Sarcophagidæ or Œstridæ.

Historical.—In 1905 Kayser studied this form of myiasis and Portschinsky in 1913 reported some cases. Malgahaes has investigated this disease in Brazil. In 1913 Grünberg found a larva of a species of hypoderma in the anterior chamber of the eye of a girl.

Ætiology.—The larvæ so far recognized as causing this form of myiasis are:—

Sarcophagidæ :—
Wohlfartia magnifica (Schiner, 1862).
Necrobia, sp ?

Œstridæ :—
Œstrus ovis Linnæus, 1761.
Dermatobia cyaniventris Macquart, 1843.
Hypoderma, sp. ?

Symptomatology.—This varies from the discovery of a larva lying like a foreign body under the eyelid, to infection of the lachrymal sacs or the tissue under the palpebral or ocular conjunctiva, to the total destruction of the eyeball.

Treatment.—This consists of the prompt removal of the larva by surgical means.

Prophylaxis.—The prophylaxis consists of prompt treatment of conjunctivitis and the protection of the head when sleeping out of doors. Natives wrap themselves up completely when sleeping out of doors.

URINARY MYIASIS.

Definition.—Urinary myiasis is the invasion of the urinary passages, particularly the urethra and bladder, by dipterous larvæ, especially those of the Anthomyidæ.

Historical.—This form of myiasis is rare, but has been recorded by Ambrose Paré in 1582 and by Turner in the seventeenth century, when he recorded two cases, while in 1909 René Chervel analyzed all cases reported up to that date, and concluded that, of twenty reported cases, six were genuine, ten were probable, and four were doubtful. He also added one of his own observation. King, in 1914, reported an American case. Palmer and Austen have recorded a case in England. Hagen has also drawn attention to a case in Boston.

Ætiology.—It is thought that the flies deposit the eggs near the meatus urinarius, and that the newly-born larvæ pass up into the urethra. Sleeping in the open is generally accused as the method of infection, but paralyzed persons become infected, especially those with urinary troubles. The larvæ which so far have been recognized are those of *Fannia canicularis* Linnæus, 1761, and *Fannia scalaris* Fabricius (p. 852).

Symptomatology.—Generally the larvæ are discovered accidentally when passing urine, when they may cause some slight obstruction.

Treatment.—This apparently is unnecessary, as the larvæ come away without causing harm.

VAGINAL MYIASIS.

Definition.—Vaginal myiasis is the invasion of the vagina by the larvæ of dipterous insects, especially those of the Muscidæ.

Historical.—This form of myiasis appears to be rare, but Cipriani, in 1902, came across a case which had a recto-vaginal fistula, and Castellani saw two cases in Ceylon, but the larvæ were not identified, except *Sarcophaga carnaria* Linnæus, 1758. In 1912 Pieter reported the presence of *Chrysomyia macellaria* Fabricius, 1794, in the vagina of a beggar-woman, and Low has seen a similar case in the West Indies.

Symptomatology.—There is a thick purulent discharge containing the larvæ, and some ulcerations deep in the walls of the vagina.

Treatment.—Vaginal douches with an antiseptic are recommended.

Prophylaxis.—Recto-vaginal fistulæ should be operated upon.

ORO-GASTRO-INTESTINAL MYIASIS.

Definition.—Intestinal myiasis is the invasion of the intestine by the larvæ of certain species of flies, but especially by those belonging to the genera *Sarcophaga* (p. 830), *Fannia* (p. 852), and *Aphiochæta* (p. 824).

History.—Many stray cases of myiasis—*e.g.*, Jenyns (1839)—have been reported from time to time, but these have been gathered together by Portschinsky in 1879 in the twelfth volume of the *Horæ Societis Entomologicæ Russicæ*, by Huber in 1899 in *Bibliographie der Klinischen Entomologie*, Heft 3 (Diptera), and by Calandruccio in the same year in the *Archives de Parasitologie*; by Pfeiffer in 1900 in his work *Fliegenlarvæ als gelegentliche Parasiten des Menschen*; in 1901 by Thébault in the *Archives de Parasitologie*; also by Wellman, and by Austen in an excellent paper read before the Society of Tropical Medicine and Hygiene of London in March, 1910. Cases are also referred to by Splendore (*Arch. de Parasitologie*, 1910), by Garrod, and by Soltau in the *Journal of Parasitology*, 1910. We have seen several cases in Ceylon and in the Balkans. Cases have been reported in England by Stephens (1905), Hewitt (1909), Cattle (1906), Garrod (1909), Soltau (1910), and Austen (1912).

Ætiology.—Intestinal myiasis may be produced by the larvæ of the following species:—

Sarcophagidæ:—
Sarcophaga carnaria Linnæus, 1758.
,, *hæmorrhoidalis* Fallen, 1810.
,, *hæmatodes* Joseph.
,, *affinis*.
,, *magnifica* Schiner, 1862.
,, *wohlfarti* Portschinky, 1875.
,, *latifrons* Meigen.
,, *ruralis* Fallen.
,, *meigeni* Schiner.
Cynomyia mortuorum Linnæus, 1761.

Anthomyidæ:—
Fannia canicularis Linnæus, 1761.
,, *incisurata* Lett.
,, *manicula* Meigen.
,, *saltatrix*.
,, *desjardensii*.
Hydrotæa meteorica Linnæus.

Muscidæ:—
Musca domestica Linnæus.
,, *corvina* Fabricius.
,, *nigra*.
Cyrtoneura stabulans Macquart.
Pollenia rudis Fabricius.
Calliphora vomitoria Linnæus, 1758.
,, *erythrocephala* Meigen.
,, *azurea*.
Lucilia cæsar Linnæus.
,, *regina* Macy.
Chrysomyia polita Linnæus.
Teichomyza fusca Macquart (?).

Tachinidæ:—
Tachina larvarum Meigen.

Micropezidæ:—
Calobata cibaria Meigen.

SYRPHIDÆ:—
Eristalis tenax Fabricius.
,, *arbustorum* Fabricius.
,, *dimidiatus*.
Helophilus pendulinus Meigen.

PHORIDÆ:—
Aphiochæta ferruginea Brunner.
Phora rufipes Meigen; synonym, *P. pallipes* Latreille.

THEREVIDÆ:—
Thereva nobilitata.

SEPSIDÆ:—
Piophila casei Linnæus.

DROSOPHILIDÆ:—
Drosophila funebris Meigen.
,, *melanogastra* Brunner.

ŒSTRIDÆ:—
Spilogaster divisa Meigen.
Gastrophilus pecorum.

Sometimes more than one species may be found in the same case.

Rarer forms of myiasis are those by larvæ of the Tipulidæ, by eggs and larvæ of the Culicidæ, and by the bots of *Gastrophilus equi*.

The eggs or larvæ of the above-mentioned flies enter the alimentary canal with the food, especially with vegetable food in an uncooked or partially cooked condition. Another method is for the fly to deposit its eggs on the nostrils and lips of children, from which they pass into the stomach and intestines, and a third method is entry of the larvæ into the rectum while using a privy. Intestinal myiasis is not uncommon in cattle, both in the Temperate Zone and in the tropics. There seems to be no doubt that the larvæ can live for a considerable time in the intestine, but the most marked example of this is *Aphiochæta ferruginea* Brun, which is believed to be capable of passing through its entire life-cycle in the human colon, because both newly hatched and fully grown larvæ were passed by a patient every two months for nearly a year, notwithstanding the fact that nothing was said to be eaten which could have contained either eggs or larvæ. It is stated that species of the Phoridæ have been found in corpses, and it has been stated that the living larvæ, pupæ, and imagines of species of *Conicera* were found in numbers in a corpse exhumed at La Fayette, Indiana, U.S.A., two years after burial.

If there is any truth in this statement, it proves that the life-cycle of these flies can be completed in a parasitic state, and would explain the possibility of a patient suffering from myiasis for twelve years, and during treatment passing 1,000 to 1,500 larvæ. Fenwick also reports cases in which it seemed probable that the whole life-cycle was completed in man. It is obvious that these statements require careful confirmation by other similar cases before they can be accepted without reservation.

Pathology.—The larvæ usually cause gastro-intestinal symptoms. Those of the Muscidæ may cause little or no disturbance, but those of the Œstridæ and Tipulidæ cause much disturbance.

Morbid Anatomy.—We are not acquainted with the details of any post-mortem examination in man, but in dogs the mucosa of the intestine is congested and marked by numerous small hæmorrhages, and it is thought that bacteria may enter the blood through these wounds.

Symptomatology.—After an incubation period varying from four to twelve days after the ingestion of the eggs, the patient, who has either felt quite well or has suffered from vague abdominal pains and anorexia, begins to feel ill with general malaise, headache, thirst, and faintness, and in children with rigors, convulsions, and even delirium. Vertigo may be felt, and generally there is some fever, which may last two to ten days or longer. Sometimes the continued fever and the diarrhœa renders the diagnosis of enteric fever probable. Pains vary from vague sensations to violent colic. Retching and vomiting may occur, and sometimes hæmatemesis, while dysenteric-like symptoms may also occur. When the larvæ attain maturity, they are sometimes violently evacuated.

Diagnosis.—The diagnosis can only be made by *repeated* examination of the motions and the discovery of the larva, the nature of which may be determined in the same way as in nasal myiasis (p. 1621). Care must be taken that the larvæ really come from the bowels, and are not contaminations of the fæces.

Prognosis.—This is good.

Treatment.—The bowels should be cleared with a dose of castor oil and then an anthelmintic—*e.g.*, Filix mas—should be administered. Thymol or santonin may also be used.

Prophylaxis.—All vegetables should be carefully washed and by preference cooked before being eaten, and fresh salads should be avoided.

Ovænya.

This word means maggots, and is applied, according to Wellman, by the natives in Angola to an alimentary canal myiasis associated with dysenteric symptoms and caused by *Fannia desjardensii* Macqu . It is easily treated by castor oil.

Muculo.

This is the African myiasis, concerning which the editors of the *Journal of Tropical Medicine and Hygiene* asked for information in 1907, but which so far has not been traced.

THE EXTERNAL OR DERMAL MYIASES.

These are the infections of the skin, whether wounded or not by dipterous larvæ. There are two varieties of this type—viz., traumatic dermal myiasis and subcutaneous myiasis.

Traumatic Dermal Myiasis.

Definition.—Traumatic dermal myiasis is the invasion of wounds or ulcers of the skin by the larvæ of dipterous insects, principally belonging to the Muscidæ and Sarcophagidæ.

Historical.—One of the earliest publications with references to this is Joseph in his 'Myiasis Externa Dermatosa,' published in Hamburg in 1800, but a large number of observations have been published since then.

Ætiology.—The larvæ which have been recognized so far are:—

Muscidæ (Subfamily: Muscinæ):—
  Chrysomyia macellaria Fabricius.
  Chrysomyia viridula Robineau-Desvoidy.
  Calliphora, sp. ?
  Lucilia argyrocephala Macquart.
  Lucilia, sp. ?
  Cordylobia anthropophaga.
  Musca putrida.

Sarcophagidæ :—
  Sarcophaga carnaria Linnæus, 1758.
    ,, *magnifica* Schiner, 1862.
    ,, *ruficornis.*
    ,, *chrysostoma* Wiedemann.
    ,, *plinthopegga* Wiedemann. (The adult is one of the 'yaws flies' of Dominica.)
    ,, sp. ?

Symptomatology.—The larvæ accentuate the putrid condition of the sores and the sufferings of the patient.

Treatment.—Antiseptic douches, syringing, with removal of the larvæ, and subsequent antiseptic dressing.

Prophylaxis.—The myiasis can, of course, be prevented by simply applying aseptic dressings to wounds.

Subcutaneous Myiasis.

Synonyms.—Cutaneous myiasis. *French*, Myase cutanée, Myase furonculeuse, Myase rampante sous-cutanée; *Italian*, Myasis cutanea; *German*, Myasis.

Definition.—Dermal myiasis is the invasion of the skin by the larvæ of species of the Œstridæ, especially by *Dermatobia cyaniventris* Macquart, 1843, and by those of the Muscidæ, especially *Cordylobia anthropophaga* Blanchard.

Remarks.—It is necessary to be careful to consider the zoological region when determining the species of the fly to which a maggot found in a case of dermal myiasis belongs, as it is unlikely that a species known to occur in Africa will be found in America, and *vice versa*. Further, it is desirable to determine definitely the nature of the fly causing the myiasis, and therefore this should be bred out as described in the opening sections of this chapter.

Ætiology.—The following larvæ are known to cause subcutaneous myiasis in man:—

Œstridæ :—
Hypoderma bovis de Geer.
Hypoderma lineata de Villiers.
Hypoderma diana Brauer.
Dermatobia cyaniventris Macquart, 1843; synonym, *D. hominis* (Linnæus junior, 1781).
Dermatobia (?) *keniæ* Kolb.
Œstrus (*Cephalomyia*) *ovis* Linnæus.

Muscidæ (Subfamily Calliphorinæ):—
Cordylobia anthropophaga E. Blanchard.
Cordylobia rodhaini.

The life-history of the œstridæ is curious, as will be discussed below. With reference to *Cordylobia anthropophaga*, by a mistake the cutaneous myiasis of Natal, Rhodesia, British Central Africa, Uganda, and the Sudan, was assigned to *Bengalia depressa*, while it should have been placed under this heading.

Varieties.—As geographical distribution is important from the point of view of the causal parasite, it appears to us to be convenient to utilize this and to divide the subcutaneous myiases into the American, the African, the Asian, and the European, while the last variety is not geographical, but pathological—viz., creeping eruption.

American Dermal Myiasis.

Synonym.—Neotropical dermal myiasis, Dermatobiasis.

Definition.—Dermal myiasis as seen in Tropical America is caused by the larva of *Dermatobia hominis* (Linnæus junior, 1781), better known as *Dermatobia cyaniventris* Macquart, 1843, and perhaps by other allied, but as yet unknown, forms.

Nomenclature.—The fly which causes this myiasis has a large number of scientific and popular names:—

Scientific Names.—*Dermatobia hominis* (Linnæus junior, 1781); *Œstrus hominis* Linnæus junior, 1781; *Œ. humanus* Humboldt and Boupland, 1805; *Cuterebra hominis* (Linnæus junior) Say, 1822; *Œstrus guildingii* Hope, 1837; *Dermatobia cyaniventris* Macquart, 1843; *Cuterebra noxialis* Gondot, 1845; *Dermatobia mexicana* Serna, 1896.

Popular Names.—*Brazil*, húra (boil), verme, berne or berme: *British Honduras*, beef worm, cormollote; *Colombia and Venezuela*, gusáno, husano (worm), gusáno de monte (forest worm), gusáno peludo (hirsute worm), gusáno macaco (macaw worm, because it attacks the macaw-headed Capuchin monkeys); *Costa Rica*, torcel; *Guatemala*, colmoyote; *Pungoa*, mirunta; *Mayan name*, suglacura.

Names Suggestive of Mosquito Carriage.—*Mexico*, moyocuil (flyworm), gusáno moyocuil (maggot flyworm); *Colombia, Venezuela, and Guatemala*, gusáno de zancudo (maggot of mosquito); *Dutch Guiana, Trinidad*, mosquito worm.

History.—In 1569 Friar Pedro Simon appears to have been the first to have drawn attention to this myiasis as seen along the banks of the Rio Magdalena and the low plains to the east of the Andes. He was followed in 1653 by Father Bernabé Cobo, who reported its occurrence in the Mexican lowlands in the coast district of Alvarado, in the state of Vera Cruz. In 1745 De la Condamine reported it from French Guiana, as did Arture in 1757. In 1781 Linnæus junior reported it from Peru and gave a brief mention of the fly, while in 1822 Say gave a description of the larva as received from South America. In 1835 Hope gave an account of the larva from under the skin of the head of a man from Trinidad. The specimen was deposited in the museum of the Royal College of Surgeons of England.

From that date scattered, but fairly numerous, references can be found—*e.g.*, Hill (1830), Guyon (1835), Gondot (1845), Coquerel (1859), Laboulbène and Davaine (1860), Bonnet (1870), Der Verteuil (1884), Ormerod (1886), etc.—until between 1890 and 1896 Blanchard published a résumé of known facts, then a series of admirable investigations upon the subject: and in 1915 Sambon again gathered together known facts, together with the history of the mosquito carriage of the eggs, and extended this with his own personal observations.

With reference to the mosquito carriage, it is remarkable to note that Father Cobo, in 1653, says that each wound produced by the common mosquito produces *within the flesh a spine-covered worm the size of a haricot bean or even larger.*

In 1911 Morales of Guatemala first described the transmission of the eggs as being due to a mosquito, and performed an experiment on a man, first noting the escape of the larva from the egg carried by a living mosquito when placed on the palm of the hand, then allowing this larva to wander about the forearm, and then scratching the skin and watching the larva burrow in, then noting the gradual development of the furuncle, and finally, when threatened with suppuration, removing the larva, transplanting it into the back of a rabbit, and watching its escape as a nymph. Also in 1911 Tovar of Maturin, in Venezuela, had noted this mosquito carriage, which was also studied by Blanchard in 1912, Rincones, Zepeda, and Surcouf in 1913, and Sambon in 1915.

Climatology.—The causal agent being a neotropical insect, the distribution of the disease is confined to Tropical America, in which it occurs in the lowlands along the coast and also in the valleys of the river, but it is absent in the hills and mountains. It begins near the southern borders of the United States, being found in Mexico, in Central America—*i.e.*, British and Spanish Honduras, Guatemala, Nicaragua, Costa Rica, and Panama: in South America —*i.e.*, Colombia, Venezuela, the Guianas, Brazil, and Peru; while it is known to occur among the West Indian Islands near South America—*e.g.*, Trinidad.

It requires a warm, moist climate, with surface water and forest vegetation.

Ætiology.—The cause of the disease is the invasion of the body by means of the larva of *Dermatobia hominis* (Linnæus junior, 1781).

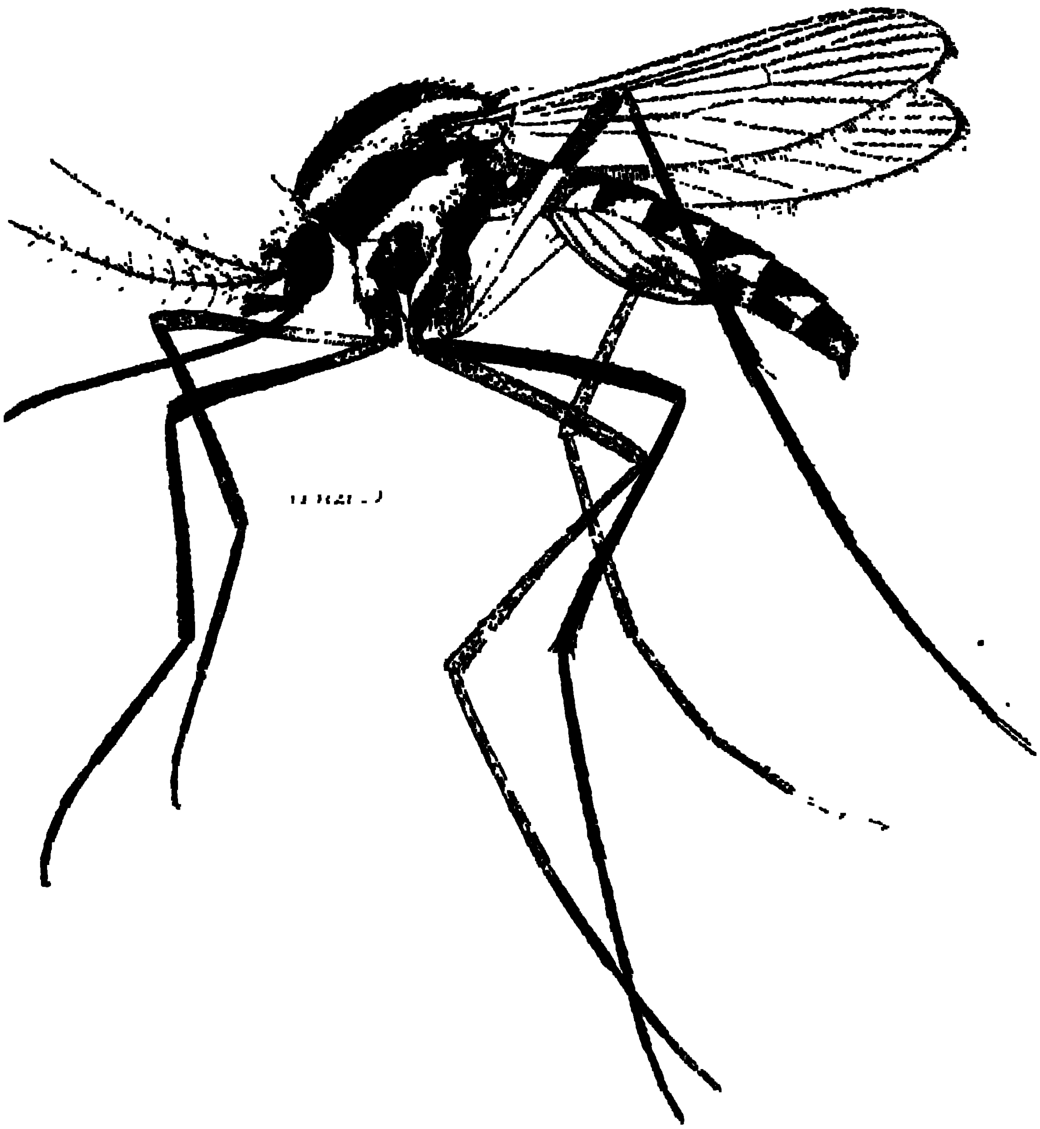

FIG. 724.—*Janthinsoma lutzi* THEOBALD, CARRYING 1 EGGS OF *Dermatobia hominis* LINNÆUS JUNIOR.

(After Sambon.)

On the evidence at present available it would seem that the fly seizes the female mosquito of the species *Janthinsoma lutzi* Theobald and attaches her eggs to the ventral aspect of the abdomen, but it has been suggested that it deposits the eggs upon foliage, and these accidentally reach the mosquito, which appears hardly probable.

When the mosquito feeds upon man or animals the little larva which has been held in position in the egg by its spines slips out and pierces the skin by means of the aperture made by the mosquito bite.

Pathology.—As it escapes from the egg, the larva possesses, in addition to the numerous spines on its first seven segments, a crown of large black rose thorn-shaped spines along the anterior border of the fifth, sixth, and seventh segments, while the last shows two posterior stigmata. When it has pierced the skin the spines on the fifth to seventh segment are shed (they are no longer required, as their function is to keep the larva in the egg-case), and the stigmata become three in number. What happens to the larva in the body is not known, but that it can wander under the skin is known, and its production of the warble and escape therefrom is also known.

Symptomatology.—*The incubation period* or time between the infection and the first appearance of the warble is unknown.

Appearance of the Warble.—Suddenly the patient feels a sharp pain in some region of the skin. It may last two to three minutes, and then pass away, but after a time it will return either in the morning or in the evening. These intermittent seizures will continue, and the pain will increase as the little rounded swelling which appears in the affected region increases in size. This swelling is the warble.

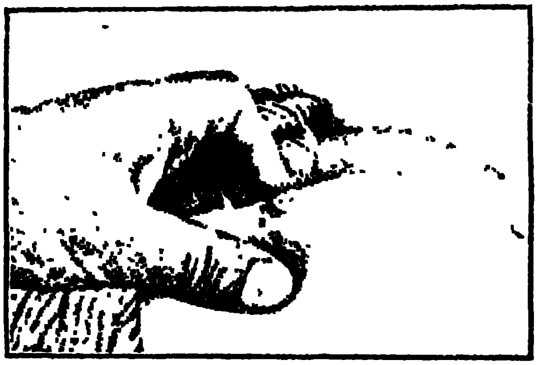

FIG. 725.—WARBLE CAUSED BY *Dermatobia hominis* (LINNÆUS JUNIOR) (After Sambon

The Warble Stage.—When fully developed the warble resembles a boil being some 2-3 centimetres in diameter and of a dark red or bluish-red colour. At the apex there is a more or less centrically placed small circular aperture which increases till it reaches a size of 3-6 millimetres. It is usually covered by a scab, which, if removed, shows a moving body with two small brownish-yellow spots. This is the posterior end of the larva. These warbles may be single or multiple, placed in close proximity or scattered, with usually only one larva to a warble, but sometimes with more and rarely as many as five larvæ to one warble. Warbles may exist in any part of the body, but are more painful in regions like the nose. Usually there are no constitutional symptoms, but there may be slight fever, and there may be swelling of the surrounding subcutaneous tissue, especially in the head, where the œdematous swelling may be limited by the adhesions of the fasciæ. When the warble is mature the larva may be seen actively moving up and down like a jack-in-the-box, appearing and disappearing from the aperture. In due course it gradually dilates the opening in the warble by means of its posterior end, and eventually escapes and, falling to the ground, crawls away and becomes a pupa.

Post-Warble Stage.—After a period varying from six weeks to six months the larva escapes and leaves behind an empty cavity, which is closed by granulation tissue and heals, leaving a hardly visible scar.

Complications.—Secondary bacterial infections may take place, giving rise to erysipelas, tetanus, lymphangitis, and enlargement of the lymphatic glands. If the larva dies an abscess is formed.

Diagnosis.—The cardinal points in the diagnosis are:—

1. The formation of boil-like swellings on the skin.
2. The presence of an aperture at the apex of these swellings.
3. The presence of the posterior end of a larva, with its stigmata in the opening.
4. The boils forming in the neotropical zoological region.

Treatment. The native places a tobacco-leaf over the aperture in the warble, or squirts tobacco-juice therein, and after twenty-four hours squeezes the larva out.

Tincture of iodine may be used in a similar manner or 1 in 20 carbolic lotion. When the larva has departed, wash the empty warble out with antiseptic lotion and dress aseptically.

African Dermal Myiasis.

The known form of African dermal myiasis is *tumbu disease*, caused by members of the Calliphorinæ subfamily of the Muscidæ.

TUMBU DISEASE.

Definition.— Tumbu disease is an African dermal myiasis caused by the larvæ of *Cordylobia anthropophaga* E. Blanchard and allied species living under the skin.

Historical.—It was reported from Senegal, where the larva is called ' ver de cayor ' by Berenger-Féraud, and later by E. Blanchard from Natal, when it was called the Natal worm, while the fly was named *Ochromyia anthropophaga*. A similar larva was found in the arm of Commander Lund in the Congo, and was long known as Lund's larva until it received the name *Cordylobia rodhaini* Gedoelst, 1905.

In 1901 it was reported that there was a maggot fly in Natal, limited to the coast, not extending inland, and not rising higher than 1,000 feet. It was also found about Delagoa Bay, in Rhodesia, British Central Africa, Uganda, and the Anglo-Egyptian Sudan. Unfortunately this fly was recognized as Walker's *Bengalia depressa*, when it was really the well-known *Cordylobia anthropophaga*, and the true Bengalia is altogether a different genus, probably an Auchmeromyia with an unknown life-history. It also occurs in late German East Africa, where it was called *Ochromyia anthropophaga* by Grünberg and *Cordylobia grünbergi* by Doenitz.

Austen has described a third species, *Cordylobia prægrandis*, in Nyasaland, Cape Colony, Transvaal, Natal, North-West Rhodesia, and late German East Africa, and contributed a valuable paper on the whole subject in 1908 to the *Journal of the Royal Army Medical Corps*: while Smith described the symptoms of the disease in the same journal.

In 1913 Rodhain, Pons, Vandenbranden, and Bequaert, demonstrated by experiment the method of infection: and Heckenroth and Blanchard recorded four cases due to *Cordylobia rodhaini* in French Equatorial Africa.

Climatology.—Tumbu seems to be widespread throughout tropical Africa, extending from Senegal in the north to Natal in the south, and from the west to the east coasts.

Ætiology.—The cause of the disease is the invasion of the subcutaneous tissues by the larva of *Cordylobia anthropophaga* and allied species. The method of infection, thanks to the labours of Smith in 1908, and Rodhain, Pons, Vandenbranden, and Bequaert in 1913, is fairly well known.

The eggs are apparently sometimes laid on the clothing, the fly, perhaps, being attracted by the odour, or perhaps at other times the egg is laid in dirt or fæcal matter on the floor, from which the larva wanders on to the human being, especially when using the latrine.

Having arrived on the skin of man or animals, it penetrates this by means of its buccal hooks, but seems to require a long time to do so, as one experiment took six hours. If this is really so, then there must be some ancillary process, as this is not natural.

Monkeys, goats, rabbits, dogs, and cats are also attacked.

Symptomatology.—During the attack slight pricking sensations may be noted. The parts most affected are the scrotum, thigh, and buttocks in Europeans, but the forearm, axilla (especially in natives), and the head also may be invaded. The infected area presents the appearance of a boil, in the central portion of which there is an opening, more or less clearly defined, which is marked by black matter (the excrement of the larva). In this hole the posterior end of the larva may be noted, and on pressing on it considerable pain is produced, probably due to the movements of the larva. Surrounding the central opening is an inflamed area about ¾ inch in diameter. The opening may, however, be obscured by dried-up discharge. Strong pressure easily expels the maggot, so that it is seldom allowed to grow old. In children and helpless persons it may attain its full size, and is then usually associated with suppuration, and when full grown is about 12 millimetres in length, of a yellowish-white colour, and bluntly pointed anteriorly, while it possesses twelve segments, on the posterior aspect of the last of which are the two posterior stigmatic plates, which are visible in the orifice of the swelling, appearing and disappearing after the manner of a jack-in-the-box.

Treatment.—The larva is easily expressed by strong pressure, and then the resulting hole can be cleansed with antiseptic solutions and the wound dressed aseptically.

Asian Dermal Myiasis.

Myiasis has not been sufficiently studied in Asia, though it is fairly common there. ***Sarcophaga ruficornis*** is reported as causing occasionally a very severe form of cutaneous myiasis, but beyond this much cannot be said.

European Dermal Myiasis.

The myiasis of Europe scarcely comes under the scope of tropical medicine, but it may be mentioned that dermal myiases are known to be caused by *Hypoderma bovis* de Geer, 1776 (p. 826): ***H. diana*** Brauer: *H. lineata* de Villers, 1789; *Gastrophilis* ***nasalis*** Linnæus, 1758: *G. hæmorrhoidalis* Leach, 1761: *G. veterinus;* and ***Lucilia sericata.***

Creeping Eruption.

Synonyms. Creeping disease, Larva migrans *Bulgarian*, Nova Bolest, Pulzasta Bolest, *German*, Hautmaulwarf, Kreechkrankheit, Hautkratzschorf.

History.—This disease was first described by A. Lee in 1875. Later on, Procke, Blanchard, Topsent, Fülleborn, and others have recorded several cases It is not rare in some parts of Europe, Africa, and Asia, and in South America. We have seen numerous cases in Ceylon. It is extremely rare in North America.

Ætiology and Pathology.—Larvæ of the genera *Gastrophilus, G. hæmorrhoidalis* and ***G. nasalis, Œstromyia satyrus***, *Hypoderma bovis, and H. lineata* have been found in several cases. In others no larva whatever was found. Looss states that the same clinical picture may be caused occasionally by Ancylostoma and Strongyloides (*Anguillula*) larvæ, or even by an inanimate object like a piece of horsehair. A larva has been found 2 millimetres from inflamed end, under a small dark spot.

Symotomatology.—The eruption is characterized by the presence of a narrow raised red line, ¼ to 1 inch broad. This line extends daily one or several inches, and is generally sinuous, but may be straight. While the advancing end progresses, the opposite end slowly fades away. The duration of the malady is long, generally several months, but occasionally two or three years. There is much pruritus.

Treatment.—Hypodermic injections of various disinfectants have been tried, with little success. Hutchins recommends a cocaine injection, followed by the injection of 1 or 2 drops of chloroform.

ALLIED CONDITIONS.

Allied to the myiases are infestations by the larvæ or imagines of the Lepidoptera, Coleoptera, Diplopoda, Chilopoda, and Dermoptera.

Scolechiasis.

Synonym.—Scholechiasis.

Definition.—Scolechiasis is the invasion of the body by the larvæ of the Lepidoptera.

History.—Originally the term 'scolechiasis' was used by Kirby and Spence for the invasion of the body by the larvæ of any insects, but Hope suggested that the term should be restricted as indicated, and invented new terms for other infestations.

Varieties.—Hope gives a list of seven cases, of which five were gastro-intestinal, one was rhinal, and one was not classified.

Gastro-Intestinal Scolechiasis.—This is due to *Pontia brassicæ* Linnæus, belonging to the Papilionidæ, and observed by Calderwood in Scotland. Two were due to *Crambus pinguinalis*, of the Noctuidæ, one being observed by Linnæus in Sweden and one by Church in England, and one was due to *Phryganea grandis*, observed by Church in England. The one without determination was found by Lister in England.

Rhinal Scolechiasis.—There is only one case caused by *Crambus pinguinalis*, and recorded by Kirby and Spence, on the authority of Fulvius Angelinus, as occurring in Ravenna.

Canthariasis.

Synonym.—Scolechiasis as used by us in the second edition.

Definition.—Canthariasis is the invasion of the body by the larvæ of the Coleoptera.

Remarks.—The term used above was introduced by Hope in 1840, when he recorded a number of cases of rhinal, gastro-intestinal, and urinary infestations.

RHINAL CANTHARIASIS.—This was due to *Tenebrio moletor* Linnæus, and was recorded by Tulpius and by Oswald Allen.

GASTRO-INTESTINAL CANTHARIASIS.—The genera recorded are numerous.

Carabidæ.—*Sphodrus leucophthalmus* by Paykull in Sweden, in 1797; *Dermestes lardarius* by Otto and Chichester, in 1807, in England; and *D. murinus* by Otto, also in England.

Staphylinidæ.—*Pæderus elongatus* Fabricius; *Oxyporus subterraneus* Fabricius; *Staphylinus splendens* Fabricius; *S. politus* Fabricius; *S. fuscipes* Fabricius; and *S. punctulatus* Fabricius by Paykull in Sweden, in 1796-1798.

Scarabæidæ.—*Geotrupes vernalis* by Van Brommell in Sweden, in 1720; *Melolontha*, sp. ?, by Leniaout, Depalse (1817 ?), and Desvoidy in France.

Tenebrionidæ.—*Tenebrio moletor* Linnæus by Forestus, in 1568, at Brielle; by Kellie in Scotland; by Pickells and by Thomson in Ireland; by Traill and others in England; by Acrel in Sweden, in 1796.

Blapidæ.—*Blaps mortisaga* Fabricius by Pickells, Thomson, and O'Brien in Ireland, in 1827; by Bateman and others in England.

Mordellidæ.—*Mordella*, sp. ?, by Rosen, in 1752, in Sweden.

Cantharidæ.—*Melæ proscarabæus* Fabricius by Germar in Silesia, in 1816.

Circulionidæ.—*Balaninus nucum* Fabricius by Henry, Astley Cooper, and others in England, in 1805-1809.

URINARY CANTHARIASIS.—*Tenebrio molitor* Linnæus is recorded by Tulpius as occurring in the bladder of a female aged fifty years; *Balaninus*, sp. ?, by Henry and Phillips in the urinary passages of a man aged sixty-two years, in Lancashire, in 1809. King in the Anglo-Egyptian Sudan has recorded a case where the larva depicted in Fig. 460, p. 870 was passed *per urethram.*

DERMAL CANTHARIASIS.—*Dyticus marginalis* Linnæus is recorded by Hope, in 1831, in England.

Diplopodiasis and Chilopodiasis.

Diplopodiasis occurs in the alimentary canal, and is caused by *Julus terrestris* Linnæus, *J. londinenensis*, and *Polydesmus complanatus.*

Chilopodiasis occurs in the rhinal passages, where *Geophilus carpophagus* Leach, *G. electricus* Linnæus, *G. cephalicus* Wood, *G. similis* Leach, *Lithobius forficatus* Linnæus, and *L. melanops* have been found, while *G. electricus* and *S. coleoptrata*, *Chætechelyne vesuviana*, *Himantarium gervaisi*, and *Stigmatogaster subterraneus* occur in the alimentary canal.

Dermapteriasis.

Dermapteriasis of the alimentary canal caused by *Forficula auricularia* has been reported by Griffin in 1830.

CHAPTER LXVIII

POROCEPHALOSIS

Synonym—Definition—History—Climatology—Etiology—Pathology—Morbid anatomy—Symptomatology—Diagnosis—Prognosis—Treatment—Prophylaxis—References.

Synonym.—Porocephaliasis.

Definition.—Porocephalosis is the invasion of the body by the larvæ of *Porocephalus armillatus* Wyman, 1848, and *P. moniliformis* Diesing, 1836, and possibly other forms, which become encysted in the liver and lungs, and ultimately develop into nymphæ, which may, by their wanderings, cause inflammation of organs and serous membranes.

History.—*P. armillatus* was first found in man by Pruner in 1846, and has since been studied by Bilharz, Fenger, Aitken, Giard, Broden and Rodhain, Dutton and Todd, and one of us. *P. moniliformis* has been met with in Asia, and by Salm in Java. Sambon thinks that Welch's Indian parasite may have been *P. najæ* Leuckart, 1860, or *P. crociduræ* Parona, 1890, found in Blyth's musk shrew *Crocidura fuliginosa*; and that Flint's case in America may have been an infection with *P. crotali* Humboldt, 1808, but for details with regard to these parasites, see pp. 734 and 736.

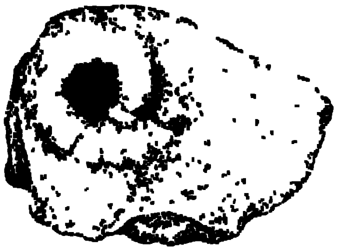

FIG. 726.—*Porocephalus armillatus* ENCYSTED IN LIVER.

(After Sambon from our West African case.)

Climatology. — *Porocephalus armillatus* is confined to Africa, being met with in negroes resident, or who have resided, therein. It has been reported from Egypt and various parts of the West Coast of Africa, but especially from the Congo.

With regard to *P. moniliformis*, it occurs in Java and the Philippine Islands. Welch described a peculiar parasite as occurring in the mucosa of the intestine of a man in India which he considered to be an *Echinorhynchus*, but which, judging from the drawing, might well be a *Porocephalus*.

Ætiology.—The adults of both *P. armillatus* and *P. moniliformis* live in the nasal cavities and lungs of pythons and snakes, and though the life-history is as yet unknown, it is quite possible that

Sambon's suggestion that the ova pass into the drinking-water, and so to man, may be correct. It is possible that the eggs hatch in the alimentary canal, and that the larvæ then pass into the organs.

Pathology.—The larvæ are found lying coiled in cysts in the liver and lungs. In due course these larvæ become nymphæ, which leave the cysts and wander through the body, appearing in the lungs and bronchi, causing bronchitis and broncho-pneumonia; in the peritoneal cavity, causing peritonitis; in the bowels, causing irritation. Perhaps they leave the body by the fæces; perhaps, also, by the sputum; but in any case they cause serious illness in, and death of, the victim.

Morbid Anatomy. In opening the abdomen, the nymphæ may be found quite free in the peritoneal cavity, and may crawl up the hands and arms of the pathologist. They may also be found in the lumen of the alimentary canal, in the mucosæ, and thickness of the wall of the bowel. The larvæ may be seen encysted in the liver and lungs.

In the cysts they lie in a curved position, with the ventral surface on the outer aspect of the curve. The lungs show signs of bronchitis and pneumonia, and the peritoneum is usually chronically inflamed, but not always.

Symptomatology.—The symptoms of the early stages of the disease are at present quite unknown, but the terminal symptoms are emaciation and weakness, associated with attacks of bronchitis, pleurisy, or other respiratory symptoms. There may be cavities in the lungs, and the sputum may be offensive and may contain the parasites, of which as many as 75 to 100 have been recorded as being expectorated by a single patient. The liver is usually considerably enlarged.

Diagnosis.- The disease has often been mistaken for phthisis; therefore any patient in the tropics suffering from the usual symptoms of phthisis associated with enlargement of the liver may be suspected, and the sputum and fæces carefully watched for the possible appearance of the parasites. When a parasite is found, it may not necessarily be either *P. armillatus* or *P. moniliformis*, but is more likely to be some form found in some animal which lives in the region where the patient resides or works.

Prognosis.—The disease is generally chronic. The prognosis is serious.

Treatment.—There is no known treatment.

Prophylaxis.—If the drinking-water is boiled or filtered, there ought to be no danger of infection.

CHAPTER LXIX

LEPROSY

Synonyms—Definition—History—Climatology—Ætiology—Symptomatology—Diagnosis—Prognosis—Treatment—Prophylaxis—References.

Synonyms.—Elephantiasis Græcorum. *French:* La Lèpre. *Italian:* Lebbra. *German:* Aussatz. *Norwegian:* Spedalskhed. *Arabic:* Djudsam.

Definition.—Leprosy is a chronic general disease, caused by the *Mycobacterium lepræ* Hansen, 1874, (usual term *Bacillus lepræ*), which produces characteristic lesions in the skin, mucosæ, and nerves. The method of infection is unknown.

History.—Even at the present time there is occasionally much difficulty with regard to the diagnosis of leprosy from allied diseases, and therefore in ancient times and in the Middle Ages syphilis and skin diseases without doubt were confused with it. Hence the history is not easy to write. Nevertheless, such a repulsive and striking disease must have been noticed by the ancients, and therefore it is possible that the references in the Ebers Papyrus, and in the English Bible, the Rig Veda, and ancient Japanese books, actually refer to what we call leprosy, together with other diseases. If this is so, leprosy is indeed ancient and widespread. Certain authorities, however, are of opinion that the Hebrew word Tsaraath, which the translators of the Bible have rendered as leprosy, does not refer to such disease. It is probable that the malady passed from Egypt to Greece, and later to Italy, by means of Pompey's troops, and that it was disseminated throughout Europe by the Roman legions, by traders, and later, perhaps, by the Crusaders returning from the East. In any case, leprosy gradually increased in Europe from the days of Pompey till, in the thirteenth century, it existed to such an extent as to move Church and State alike to combat its ravages. Stern measures were enforced, and the lepers were isolated in lazarettos. They were compelled to wear a special dress, to use a clapper when passing along the roads, to only indicate with a stick the articles they desired to buy in a market; while they were forbidden to drink from public fountains, to touch children, to speak to a healthy person in a loud voice, or to eat with any person other than a leper. Further, the Church performed the Burial Service over a person who was diagnosed to be a leper, and therefore officially he was dead. The result of this appears to have been beneficial, as the number of lepers diminished rapidly in the fourteenth and fifteenth centuries, since when the disease has almost disappeared from many parts of Europe.

But while abating in Europe, it appears to have been introduced into Madeira and the Canary Islands about the end of the fifteenth century, and perhaps also into America by the Spaniards. The infection of the West Indies would appear, however, to have been mainly due to the negro slaves brought from Africa about the middle of the sixteenth century, after which the disease became common. There is great doubt as to whether it did not exist in South America in ancient times, but no clear evidence is forthcoming at present.

In India, Japan, and probably China, leprosy is most ancient, while it is very common in South China. During recent years the Chinese have been moving about the world, and are accredited with introducing the disease into Kamschatka, the Sandwich Islands, Polynesia, Columbia, California, Australia, New Zealand, and also into Indo-China.

Though very common in North and Tropical Africa, it appears to have been unknown in South Africa until introduced in 1756 by the Dutch from Java, who carried it through Cape Colony and the Orange Free State into the Transvaal. It must, however, be stated that some people think it has existed for a long time in South Africa.

It is said that the numbers of lepers have markedly increased in South Africa since the advent of the East Indian troops in the middle of last century.

As regards medical literature, Hippocrates says but little about the disease, and perhaps really refers to psoriasis, while Aristotle defines it better. It is not, however, until the first century that Aretaeus of Cappadocia gives a clear description of the disease, and not till 1847 that the first modern clinical account by Danielssen and Boeck appeared. The pathology of the disease has been carefully studied by Virchow, Vandyke Carter, Leloir, Babès, Unna, Zambaco, Innes, Campana, De Amicis, Philipson, Mantegazza, and Bergmann. In 1871 Hansen discovered the bacillus, and in 1877 definitely associated it with the causation of leprous lesions, and it has subsequently been studied by Neisser in 1879, and many others.

Many attempts have been made to cultivate this bacillus, notably by the Indian Commission, van Houten and Rost, and more recently by Keebrowsky, Clegg, Bayon, and Duval. In 1903 Stephansky and Dean, and later Rabinowitsch and Tidswell, discovered a peculiar leprosy-like disease in rats, the lesions of which contain bacilli closely resembling Hansen's bacillus in appearance, and not capable of cultivation. A diphtheroid bacillus has, however, been cultivated by Dean from two cases, and is said by him to be capable of being agglutinated by human leprous serum. There is probably no connection between the human and the rat disease, though some authorities admit it. The condition has been recently investigated by Marchoux and Sorel, Bayon, and others.

The method of infection is at present unknown, though there are various theories, more or less ably defended, which will be mentioned later. Marchoux and Bourret consider that they have successfully inoculated a chimpanzee, and Nicolle and Blaizot have produced lesions resembling leprosy in lower monkeys. The condition of the eye has been much neglected until recent years, when the researches begun by Bull and Hansen as far back as 1873 have been extended by Grossman in 1906, de Silva in 1907, but most importantly by Borthen in 1899.

Deycke and Reschad inoculated the surface cream of sterilized unskimmed milk with material obtained from the under aspect of leprotic tubercles by throwing back a flap of skin. Incubated at 30° C., a growth forms in fourteen days, which is characterized by its bright orange tint. This organism they called *Streptothrix leproides*, and from this they obtain a neutral fat, 'nastin,' which is similar to a fat found in Hansen's bacillus, and this Deycke considered to be the agent which produced favourable symptoms when cultures of *Streptothrix leproides* were injected into patients. Later he noticed that these favourable conditions were associated with a leucocytosis, and therefore used nastin mixed with cinnamic acid, which is excreted as hippuric acid, the two acids being connected by benzoic acid as an intermediate product. He therefore used benzoyl chloride to extract the 'nastin,' and injected the 'benzoyl nastin' into patients, producing a reaction. Deycke believes that the nastin is only a carrier of the benzoyl chloride to the bacilli, which it deprives of their fat, and so allows the phagocytes to attack them. Four solutions were prepared: Nastin B 0, Nastin B 1, Nastin B 2, and K., this last being only benzoyl chloride, and being used to shorten and reduce the severity of the reaction if required. The others represent nastin in varying degrees of strength, Nastin B 2 containing an excess of nastin, while Nastin B 1 is that usually employed. Unfortunately no general success has followed this line of treatment.

Climatology.—At the present time there is but little leprosy in many parts of Europe, but it is still common in Iceland, while it is found in Spain, Italy, the Balkans, Turkey, Crete, and Cyprus. It is less frequent than formerly in Norway, Sweden, Greece, and some of the Mediterranean islands, rare in France and Germany, and almost extinct in Denmark, Belgium, Holland, Austria-Hungary, and England.

It is very common throughout the whole of Asia. In Ceylon there are numerous lepers, many of whom are treated in a leper asylum at Hendela, near Colombo, which is believed to be one of the best in the world.

In Australia the disease is known principally in Queensland and New South Wales, and also in Victoria; while in New Zealand it is known among the Maoris. It occurs in New Caledonia, Tahiti, and the Sandwich Islands.

It is spread sporadically over the United States, but is rare in Canada, while it is well known in Mexico and Central America, and common in the West Indies. In South America it appears to be common in Colombia, Venezuela, the Guianas, and Brazil, but whether it is rare or simply not recognized in other countries is unknown.

It appears to be spread all through Africa, but is certainly rare in West Africa, more common in Central and East Africa, and decidedly more common in North and in South Africa, where there is the celebrated Robbin Island Leper Asylum. There are people who believe Egypt to be the original home of the disease, from whence it spread to Asia and Europe.

Ætiology.—The disease is caused by Hansen's bacillus, which morphologically has the greatest resemblance to the tubercular bacillus and is stained by the same methods.

With regard to the cultivation of the bacillus there are three views:—

1. That it has never been cultivated.
2. That it can be cultivated as a streptothrix or nocardia.
3. That it can be cultivated as a bacillus.

1. *That it has never been cultivated.*—This is still the most generally accepted view.

2. *That it can be cultivated as a Streptothrix.*—This is the view held by Bordoni-Uffreduzzi, Babès, Rost, Kedrowsky, Shiga, Hewlett, Bayon, Johnston, and others. They maintain that Hansen's bacillus in cultures becomes a filamentary branching non-acid-resisting organism, which, when injected persistently into animals, produces the signs of leprosy. From these animals, they say, it can be recovered as an acid-resisting bacillus. The strain separated by Kedrowsky, and further investigated by Bayon, is the one which in our opinion is the most important with a view to further researches. The growth of the germ is slow, and the colonies coalesce into a whitish mass. The inoculation of cultures into monkeys, rats, and guinea-pigs, gives rise, according to Bayon, to leprosy-like lesions, with very little tissue proliferation, no caseation necrosis, no vascular sclerosis, and with presence of numerous acid-fast bacilli. Serological reactions, such as agglutination and complement fixation, are rather in favour of Bayon's theory. Moreover, the inoculation of an extract of the cultures induces in leprotic patients a reaction with fever, comparable to that induced in tubercular patients by tuberculin.

In 1915 Fraser and Fletcher were unable to confirm Kedrowsky and Bayon's results, and came to the conclusion that Kedrowsky's bacillus is not the leprosy bacillus.

3. *That it can be cultivated as a Bacillus.*—This is the view held by Clegg, Duval, and others. Clegg succeeded in cultivating his bacillus in symbiosis with an amœba. The cultures are chromogenic. The inoculation of this germ apparently does not produce leprotic lesions. Duval gives importance to a non-chromogenic always acid-fast bacillus he has isolated, which grows very slowly,

and only on special media. He states that in addition to this bacillus he has at times grown a polymorphic organism, sometimes diphtheroid, sometimes streptothrical, and of varying degrees of acid-fastness. He compares this type of germ to those isolated by Kedrowsky and Bayon, and is not inclined to give it any importance.

The bacilli, which, as will be shown later, exist practically all over the body wherever diseased tissue is found, leave it by the nasal secretion, the tears, the salivary secretion, the sputum, the milk, the semen, urethral and vaginal secretions, and by the fæces, and are cast off with the scales of skin or the discharge of disintegrating tubercles. Of all these, the secretion of the nose appears to be of great importance, for, as Sticker and van Houten showed, the bacilli are very commonly met with in that situation. The bacilli are reported to have been found in *Culex pungens* and *Clinocoris lectularius* by Goodhue, of the Molokai Leper Settlement. Finally, notwithstanding one or two observations, the bacillus has never been found in earth, dust, air, water, or food.

With regard to inoculations of leprotic tissues and nodules into animals, experiments have been negative in rabbits, guinea-pigs, dogs, cats, bats, pigs, and birds, even though some experiments were thought at the time to be successful. Nicolle produced a hard indolent swelling with a few lepra bacilli by injection of leprous tissue in a *Macacus* monkey. Marchoux and Bourret have made inoculation experiments in a chimpanzee with partial success. Stanziale has inoculated leprotic material in the cornea of rabbits, inducing certain lesions which he has been able to transmit, to a certain point, from animal to animal. In rats a peculiar skin disease, somewhat resembling leprosy, occurs spontaneously, as observed by Stephansky, Dean, and Rabinowitsch. This has been investigated by Marchoux and Sorel, who have come to the conclusion that it is generally transmitted by contact, and not by parasitic agencies. They have not succeeded in cultivating the bacillus, while Bayon has cultivated a streptothrix very similar to the Kedrowsky strain isolated from human lesions.

With regard to the experimental inoculation of human beings, the only case cited as successful is Arning's inoculation of a Sandwich Island criminal in the arm with a leprous tubercle. This man developed a neuritis of the ulnar and median nerves four weeks after the inoculation, a tubercle five months later, the full signs of leprosy two and a half years later, and died a leper six years after the inoculation. It is, however, to be noted that he lived in a leprous country, and that there was leprosy in his family—facts which decrease the importance of the experiment.

There can, however, be no real doubt that the disease is in some way spread from human being to human being. In support of this there are many well-known facts—*e.g.*, the case reported by Benson, where an Irishman, having acquired leprosy in the West Indies, returned to Ireland, and died from the effects of the disease in about eleven months. During this period his brother not merely lived with him, but slept in the same bed, and, after his death, wore his clothes. In about four to five years this brother showed all the typical signs of tubercular leprosy, though he had only once been out of Ireland, and then only to visit England. Another similar case may be quoted of a person who, acquiring leprosy in Tonkin, returned to Strasburg and lived with a nephew, who subsequently developed the disease. Turning to the evidence of history, there is the spread of leprosy throughout Europe, and, later, the rapid spread of the disease in the Sandwich Islands, where, though existing probably for many years, it increased from 1859, when it was hardly known, till in 1881 no less than 800 lepers were isolated, and it is said that no less than one-tenth of the population were affected Another instance is the case of New Caledonia, in which the disease, though now common, is believed to have been introduced for the first time in 1860, and Pine Island, which is said to have been infected from New Caledonia: or Mauritius, which was infected by a single leper, and from which, later, the island of Rodriguez was infected, also by a single leper.

As to individual cases of infection by residence among lepers, the most noted is that of Father Damien de Venster, who went from Belgium as a missionary to the Molokai Leper Asylum of the Sandwich Islands in 1873, and who was first recognized to be suffering from the disease in 1882, from which he died in 1889

Again, the prophylactic success of even partial isolation of lepers, as evinced in Europe in the thirteenth and fourteenth centuries, and to-day in Norway, Sweden, and Iceland, is in favour of the view that the disease passes from man to man. But it is not wise to hastily conclude that this transference is direct, for any of the above cases are easily explicable by the disease being conveyed by food or biting animals. The success of partial isolation might be simply to diminish the chance of infection by these means. Moreover, the fact that the attendants of the Hendela Leper Asylum of Ceylon have so far not been known to contract the disease is against the theory of direct contagion. Further, though there is evidence that married people may both suffer from the disease, there is no proof that sexual intercourse is a means of infection. Nor is there any evidence of heredity being a source of infection, for never has a child been born in a leprous condition, though it is said that 10 per cent. of the children of leprous mothers become sooner or later lepers themselves.

If the germs are not carried from one person to another by contact, sexual or germinal transmission, they might still be conveyed by air, dust, water, or food, and, indeed, all these theories have their supporters.

It does not appear likely that it is conveyed by air, otherwise it would surely be spread more commonly from patients to attendants in leper asylums. With regard to dust, it is quite true that, though some persons report the presence of a very few bacilli in earth taken from places frequented by lepers, the majority have failed to find them; and, again, what has been remarked with regard to air also applies to dust. The germs have never been found in the water of the most highly infected places.

Many articles of food have been suspected, especially fish, and more particularly salted fish—a view which Sir Jonathan Hutchinson has strongly advocated: but even he admits that it will not explain all cases, particularly its presence in people who have no chance of eating cured fish.

After excluding all these, there is still the possibility of the infection being carried by some blood-sucking insect. This subject has been most ably discussed by Nuttall, who points out that Linnæus and Rolander considered *Chlorops* (*Musca*) *lepræ* to be the active agent; while Corredor suspected flies in general: Sabrazés, insects; Joly, *Sarcoptes scabiei* and *Pediculi*; and Sommer, mosquitoes. Nuttall himself says that the possibility of such transmission cannot be denied. Goodhue has demonstrated the bacilli in *Culex pungens* and in *Clinocoris lectularius*; and Marchoux and Bourret have suggested that some Simuliidæ might be the carriers of the disease. Flies, lice, bugs, fleas, ticks, etc., have all been studied recently without any great success.

It might be thought that, direct inoculation having failed, the infection by means of insects would be unlikely. But that is not so, because it is well known that the passage of bacilli through another animal may markedly modify the virulence of the germ. On the other hand, a great many facts are in favour of the insect spread of the disease—*e.g.*, the infection in a family. The cases cited above as examples of contagion would be easily explicable by the action of an insect, as would the effect of isolation in preventing the disease. Moreover, the predisposing causes of dirt, poverty, etc., are also explicable on the same reasoning, especially the curious disappearance of the disease in the families of Norwegian peasants emigrating to America, where they became much cleaner in their habits. The difficulty of cultivating the germ on ordinary media is very suggestive of its being accustomed to live solely in animal tissues; while the abundance of the bacilli in the skin is also suggestive of that being the natural method of leaving the body. Everything in the history of the disease appears to us to favour its spread by animal agency.

Cases of infection by vaccination and variolization are on record. Natives of Ceylon generally state that the disease begins after a bite by a rat.

Pathology.—According to different theories, the bacillus enters the body via the skin, the nasal or respiratory mucosæ, the alimentary canal, or the generative organs.

The list is so comprehensive that it will be obvious that the real method of entry is entirely unknown. On arrival inside the body, the bacillus is ***supposed*** to come to rest inside a lymph space somewhere, and there to grow and form colonies, from whence it can be disseminated through the body, perhaps by the blood and the lymph streams. It must be remembered, however, that the nature of the initial lesions is quite unknown. So enormously do the bacilli multiply in the body that there are few diseases which show an equal infection.

The pathogenesis of the lesions is not very well known, and there are many points of dispute which so far have not been settled. The early stages have been most carefully studied by Unna in the neurolepride, in which there is at first a dilatation of the capillary vessels of the skin, on the walls of which the typical bacilli can be found. The organisms now pass into the wall of the vessel, and appear to irritate the connective-tissue cells of the vicinity, which, becoming plasma cells, surround the periphery of the vessel.

There is a dispute as to whether any diapedesis of the white cells takes place. Thus Thin and Neisser support the view of a diapedesis, to which, however, Unna is opposed. According to the former observers, the cells of the leproma contain not merely plasma cells, but also leucocytes and lymphocytes, while according to the latter they are entirely plasma cells and their derivatives, for Unna holds the view that the bacillus has but little attraction for the white cell. The organisms pass from the vessel wall into the lymph capillaries, in which they grow. These early stages have not been seen in the typical leproma, in which the bacilli from the first are met with in the lymphatics, in which they grow luxuriantly, causing the considerable dilatation which is a marked feature of the lesion.

Now occurs a phenomenon concerning which there is much difference of opinion, for either the plasma cells increase in size, and, becoming multinucleated, engulf the bacilli, forming in this way the typical 'lepra cells' of Virchow—a view supported also by Neisser and others—or the bacilli attack the plasma cells, destroy their cytoplasm, and so damage the nucleus that it becomes achromatic and breaks into several pieces, which remain surrounded by, or on the side of, a mass of bacilli embedded in mucus, thus giving rise to a false appearance of a giant cell or chorio-plaque enclosing bacilli, as asserted by Unna and others. Unna's staining method with Victoria blue and saffranin colours normal bacilli blue, and dead bacilli yellow.

The lesions show large cells—the 'lepra cells,' containing large masses of bacilli—but in addition to these cells there are also masses of bacilli embedded in mucus, and not enclosed in cells, which are the 'globi' of older writers, and which in fresh preparations appear as large, rounded, brownish masses. Bayon believes that the bunches of bacilli arise partially by the choking of the lymphatics by phagocytes swollen by the numbers of the bacilli which they have engulfed, and partially by the endothelium of the vessel wall also becoming distended with bacilli. The nuclei of these cells degenerate and are eliminated, while the remnants of the cells, together with the bacilli, form 'the globi,' and when these remnants disappear the bacilli are left free in the tissues. The hyaline coating of many bacilli may be a product of the protoplasm of these cells or may be secreted by the bacilli themselves. Sometimes typical giant cells, called 'Langhans' cells,' are seen. Marchoux and Bourret consider the so-called lepra cells to be undistinguishable from the large mononuclear leucocytes.

The bacilli do not invade the surface epithelium, nor the layer of the cutis directly below this; nor do they affect the sweat glands, nor the hair sheaths superficial to the opening of the sebaceous glands.

The typical leproma, therefore, shows superficially epithelium, normal in every respect, except that there are no interpapillary processes. Below the epithelium there is a layer of connective tissue, free from bacilli, under which lies the typical lesion, composed of lepra cells, plasma cells, and connective-tissue cells, separated by a very slight amount of fibrillar connective tissue, and containing vessels, whose walls are thickened by an infiltration of the adventitia, media, and intima to such an extent that at times the lumen may be obliterated, while the lymphatic spaces are dilated and filled with bacilli surrounded by mucus, forming the 'globi.' Beneath the lesion the connective tissue may be more or less normal.

The attacks of fever and the erysipelatous eruptions, which will be described under the Symptomatology, are explicable by the dissemination of the bacilli throughout the body by the blood stream, the bacilli being contained in the large mononuclear leucocytes, according to Marchoux and Bourret, and by the embolism of the capillaries of the skin by bacilli and white cells, which, however, are soon recovered from.

Lesions may remain stationary for years, and retrogression may take place as the result of treatment, or spontaneously, in which case the dead bacilli are absorbed, and sac-like spaces left, which rarely become sclerosed by connective tissue. If on a surface, the leproma may soften, break down, and ulcerate, thus disseminating the bacilli in the discharge.

The bacilli may also enter into the nerves and cause a hyperplasia of the connective tissue cells of the coats and the formation of typical leproma cells at first around the vasa nervorum, and later in the perineurium and endoneurium.

These cells press on the nerve fibres, causing a degeneration of the neurilemma, and later a disintegration of the arteries and a destruction of the nerve fibres, which finally results in the nerve being largely converted into connective tissue. In places where the nerve is apt to suffer from compression or other slight injuries, it becomes so thickened as to be easily palpable—a fact which Lie explains by saying that the bacilli which he found in the cutaneous nerves pass up the nerves and become located at spots liable to injury.

It is usually believed that the nerves only are affected, and that the paralyses, etc., are the results of disease of the peripheral nerves, but it has been shown that the bacilli attack the anterior cornua of the spinal cord, and therefore this may play a part in the production of the symptoms.

The bacilli may be carried by the blood stream all over the body, but show a selective affinity for certain organs, in which they develop the typical leprotic lesions. A certain number of leprotic subjects react to tuberculin injections, and give a positive Wassermann reaction.

Morbid Anatomy.—The skin lesions which may be found are the tubercles, which may or may not be ulcerated, and the pigmented and apigmented areas. On cutting into the leproma, it is seen to be situated usually in the cutis, and covered by the epidermis; but it may lie in the subcutaneous tissue, in which case it does not form a tubercle. It is yellowish-white in colour, firm in consistency, and if squeezed, usually a little clear fluid can be obtained. It will be noted that the sweat and sebaceous glands and the hair follicles are compressed and as a rule atrophied, while vesicles and pustules may occur on the surface, which may be ulcerated and covered with crusts. The macules consist of round-celled infiltration, with but few large cells, which are generally free from bacilli. In the spots which during life were anæsthetic, which are derived from the macules, the corium is largely converted into fibrous connective tissue, which has caused glands and hairs to atrophy and disappear.

The typical lepromatous infiltration may occur, not merely in the skin, but in the mucosæ of the tongue, pharynx, larynx, epiglottis, and in the submucosæ of the intestine.

The liver, which is usually enlarged, shows a leprous infiltration of the portal systems, while the spleen, which also may be enlarged, shows the same along the course of its vessels, particularly while they are in the septa, and a similar infiltration may be seen at times around the bronchi.

The ovaries and testes may show infiltrations and fibrosis of the interstitial tissue, which destroys the secretory elements, and causes the sterility which is usually so marked among lepers. The lymphatic glands are often enlarged, infiltrated, and full of bacilli, especially the femoral. Nephritis and leprous infiltration of the kidneys may be seen. The nerves most commonly affected are the palmar branch of the ulnar, the ulnar, the median, the peroneal, posterior tibial, and the great auricular. When exposed, the nerve is seen to show a fusiform, reddish-grey swelling, which, when examined, is found to consist of lepromatous tissue lying among the nerve fibres.

In the spinal cord there may be posterior sclerosis and meningitis, though it is doubtful whether these are really due to the disease or to some complication. The cells of the posterior cornu have been said to be atrophied, as well as those of the anterior cornu, in which Lie has found bacilli.

In the circulatory organs periarteritis and endarteritis are met with, while osteomyelitis, necrosis, caries, and absorption of the bones may be seen, and will be mentioned again later. Trophic changes in the joints and perforating ulcers are met with in the nerve form of the disease.

For a long time the presence of lepromata in the lung was disputed, but recently it has been proved that the lungs can become infected with leprotic lesions. The lesions of leprotic lungs are very similar to those of tubercular lungs, but are more solid, caseate less frequently, and are less prone to be destroyed. Some of the earliest signs are petechial haemorrhages, which upon microscopical examination show a diffuse, small, round-celled infiltration, with occasionally a giant cell, but without fibrosis, but with a slight cellular exfoliation in the surrounding alveoli and congestion of the bloodvessels and capillaries. In these areas there are numerous intracellular leprosy bacilli (Wise). In addition there may be an acute and at times caseating parenchymatous inflammation or chronic diffuse interstitial inflammation. These are distinguished from similar tubercular affections by inoculation into guinea-pigs with negative results.

Symptomatology.—The *incubation period* is entirely unknown, and must necessarily remain so until the method of infection and the date of the onset of the disease is discovered; hence the statements made by the different observers that it may last for a few weeks or months up to many years. The *method of invasion* is also quite unknown. Sticker suggests that it begins with nasal symptoms—blocking of the nose, epistaxis, and frontal headache; other observers with skin eruptions. The truth appears to be that, so far, the initial lesions and their symptoms, if any, have escaped notice.

Before the eruption appears there are, in many cases, attacks of fever of an intermittent or irregular character, with a marked feeling of general illness, associated with headache and pains in different parts of the body, peculiar sensations of cold, formication or numbness in various places, and, above all, of abnormal local or general perspirations. These attacks of leprotic fever, without any definite clinical signs of leprosy, may occur at intervals for years. This fever is probably due to the dissemination of the bacilli through the body, and may represent a septicæmic process due to the *Bacillus lepræ.*

After the general dissemination through the body, the bacilli appear to settle mainly in the skin or in the nerves, though, of course, there are many cases in which they settle in both. It is therefore convenient to distinguish the two varieties of the disease, first differentiated by Danielssen and Boeck-- viz., 'lepra tuberculosa,' or 'nodular leprosy,' and 'lepra maculo-anæsthetica,' or 'smooth leprosy' remembering that the division is artificial, and that numerous cases exist which show both forms.

TUBERCULAR LEPROSY.

After repeated attacks of fever the patient has a more severe one, during which an erythematous, diffuse, or macular eruption appears on the face and limbs. The fever subsides, and the maculæ may disappear or thicken and become tubercles, which are dermal lesions projecting from the skin or mucosæ, in addition to which there are subdermal infiltrations, which can be more easily felt than seen. If they disappear, it is only for the time, as new maculæ will appear with a new attack, and sooner or later the thickening will take place, and the nodules or tubercles, typical of the disease, will appear. Each outbreak of nodules is in some cases preceded by an attack of fever, with or without an erysipelatous-like eruption in the area to be affected, associated with enlargement of the lymphatic glands. In our experience, however, the fever may be absent in many cases.

The nodules may form all over the skin, but are most common on the face and limbs In the former situation they appear on the forehead, cheeks, alæ of the nose, lobules of the ears, lips, and chin, and as they increase in size, totally alter the appearance of the patient, defacing the natural facial lines, and forming new furrows between adjacent nodules; while at the same time, in many cases, the hair of the beard, moustache, and eyebrows drops out. These changes result in the countenance becoming like that of a satyr or, when the furrows are more marked, like that of a lion; hence the terms 'satyriasis' and 'leontiasis,' which the ancients applied to the disease.

Eye lesions are more commonly met with in this form of the disease, for Borthen, as the result of his investigations, concludes that only 8·08 per cent. of women and 1·67 per cent. of men suffering from tubercular leprosy escape without some form of disease of the eyes or their adnexa. Women are, however, less affected than men, but age shows no influence on the production of eye affections. In tubercular leprosy the eye is attacked by genuine leprotic lesions, and secondary infections are rare.

The supraciliary region, as has already been mentioned, is early attacked, and complete madarosis is not uncommon, and, later, paralysis of the frontalis muscle sets in. The eyelids are often attacked by diffuse or nodular lepromata, which may be merely extensions from the disease already in the supraciliary region, or may be quite distinct lesions. As a result of ulceration of these nodules, the eyelids may be destroyed.

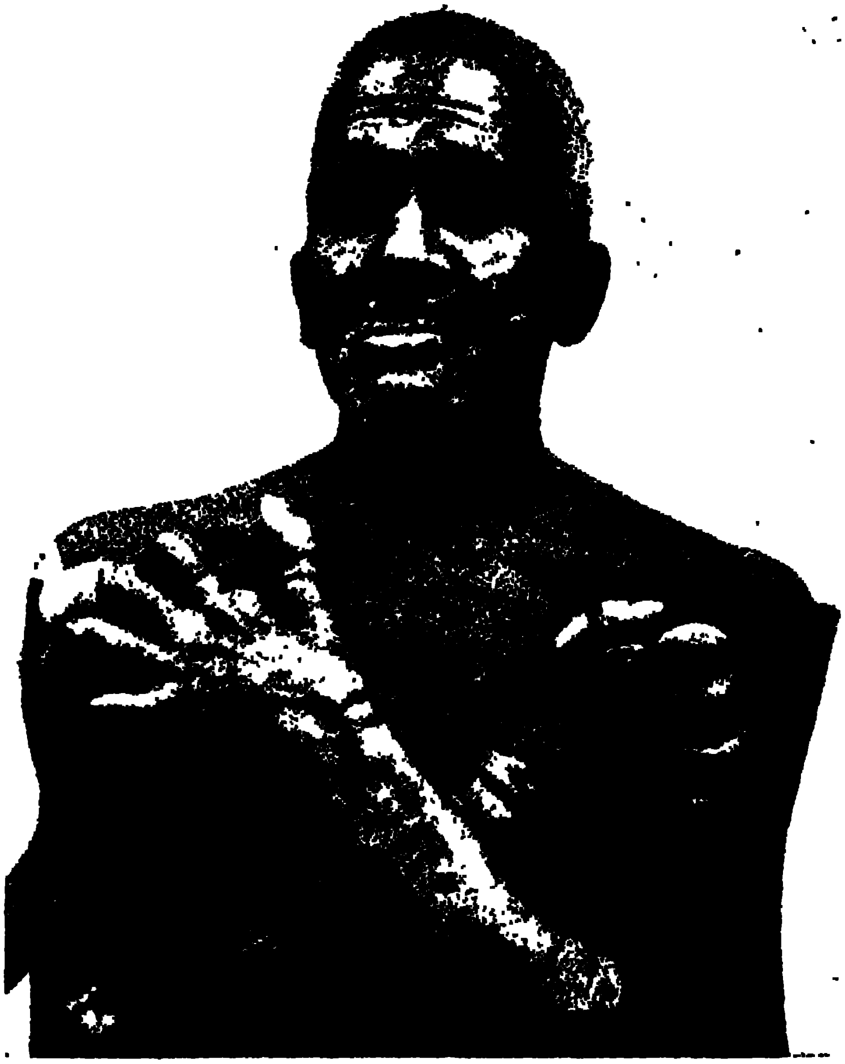

FIG. 727.—LEPROSY, SHOWING THE ERYSIPELATOUS-LIKE ERUPTION ON THE ARMS AND FACE.

The conjunctiva may be infiltrated, leading to hyperæmia, or, more rarely, anæmia, and producing lagophthalmos, ectropion, and, if cicatrization takes place, xerophthalmia.

The episclera is apt to become infiltrated along the external aspect of the corneo-sclerotic junction, resulting in white, grey, or yellow flattish masses, which spread round the cornea dorsally and ventrally, and are prone to invade its tissue in the form of a diffuse infiltration, which spreads from the outer side towards the pupil. More rarely small spots form on the cornea, giving rise to the 'keratitis punctata leprosa' of authors.

The disease may also spread to the uveal region, in the form of an infiltration, which causes an anterior or posterior iritis; or, more rarely, nodules may form in the ciliary body or near the canal of Fontana, giving rise to an irido-cyclitis or irido choroiditis.

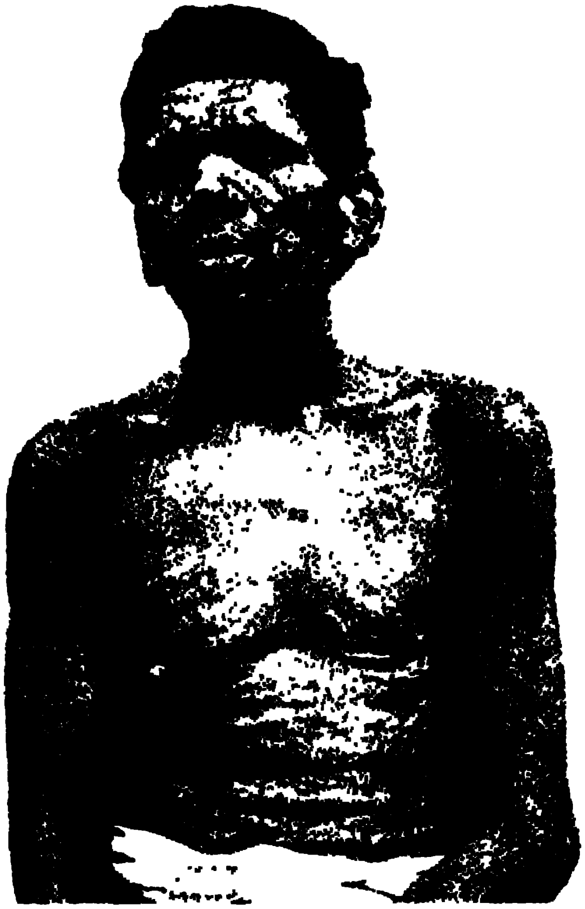

FIG. 728.—TYPICAL TUBERCULAR LEPROSY, SHOWING THE LEONINE EXPRESSION, THE THICKENED SUPERCILIARY RIDGES, AND THE MADAROSIS.

Lie has studied the pathology of these lesions, and has shown that it is rare for the optic nerve, the retina, the lens, and the vitreous humour to be affected.

The mucosæ of the nose may be attacked, with, first, blocking of the passage, and then, when the leproma extends down to the cartilage and ulcerates, falling-in or destruction of the nose, with much disfiguration of the countenance, resulting from the cicatrization which follows the ulceration. The tongue may also be affected, and show numerous tubercles, separated by furrows, or it may be simply infiltrated. The walls of the mouth and pharynx may become lepromatous, which causes mastication and deglutition to be rendered difficult, while the same condition in the larynx makes the voice raucous, and may impede respiration, especially if there is ulceration and cicatrization.

The skin of the hands, arms, and legs also shows numerous raised tubercles, which may ulcerate. The nipple is often infiltrated. The submaxillary, cervical, and femoral glands may be enlarged, and may suppurate. The testes often become fibrous, and menstruation becomes irregular and stops.

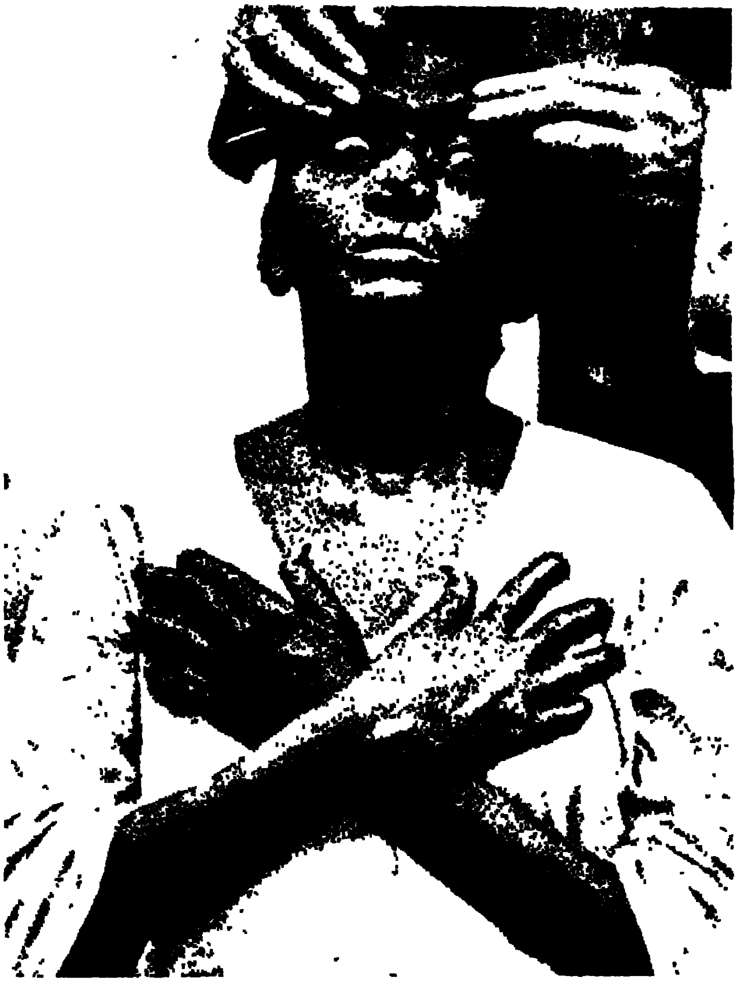

FIG. 729.—DIFFUSE INFILTRATION OF BOTH CORNEAS AND DEFORMITIES IN THE FINGERS OF THE RIGHT HAND.

Blood.—In the early stages the blood shows no changes, but later it shows a diminution in the erythrocytes and a lowering in the colour index. The red cells may show abnormalities in the form of poikilocytes, polychromatophilia, and basophilia. The number of leucocytes is generally normal, or, according to Bourret,[1] diminished; while this observer records an eosinophilia in all stages of the disease, which he says may at times be quite considerable. There may be leucocytosis during the febrile attack. Neutrophile myelocytes may also be observed. According to our researches the leucocytic formula is extremely variable, and is of no help in the

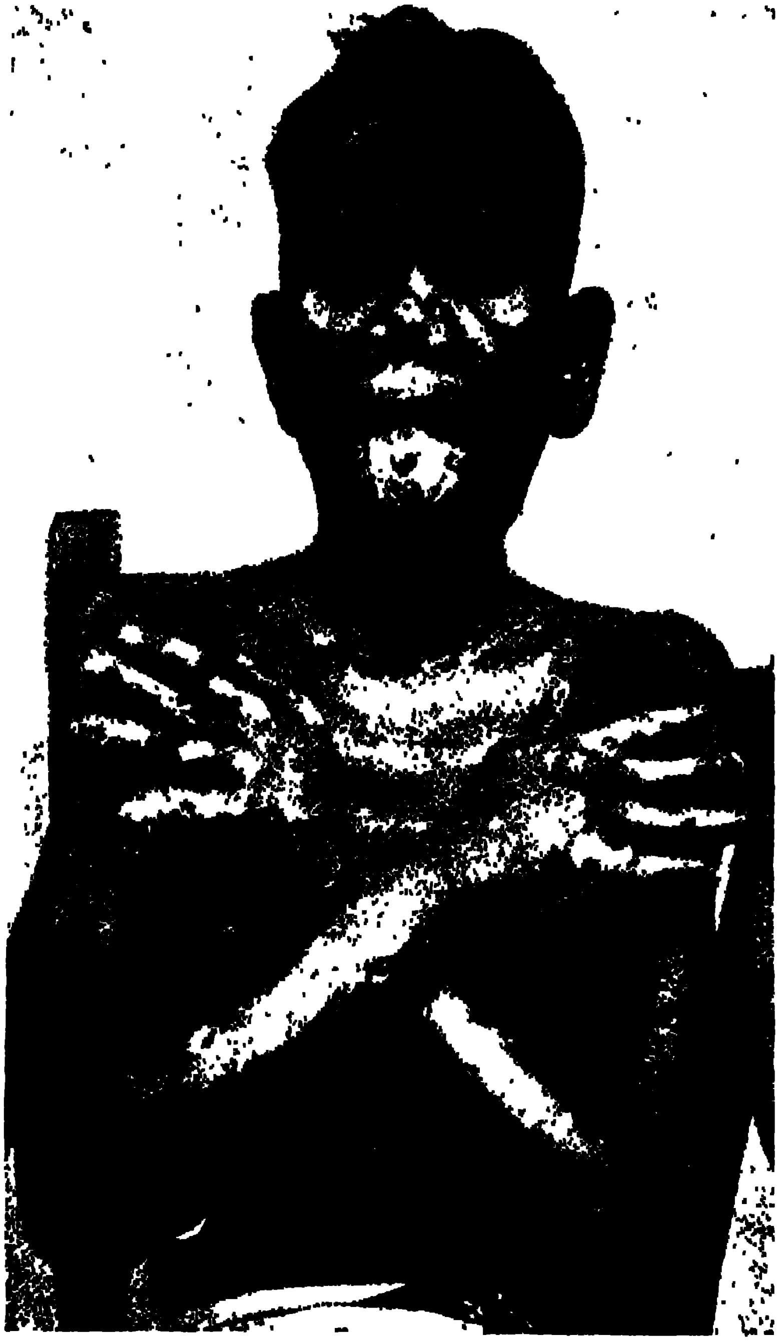

FIG. 730.—LEPROMA OF THE TONGUE.

special leucocytic index. Some authors state that they have found the specific bacillus in leucocytes, or, more rarely, free in the peripheral blood. Wassermann's reaction is, in our experience, at times present even in cases where there is no history of syphilis or yaws.

Urine.—There are not many observations upon the urine. The most marked feature is a great increase in the ethereal sulphates. Brinton, of Rio de Janeiro, has isolated two ptomaines from the urine, one allied to choline and the other to muscarine.

The nerves may become attacked, and the signs and symptoms of nerve leprosy be added to those of the tubercular, forming a variety of mixed leprosy.

The ulcerations generally become marked towards the end of the disease. If treated, they cicatrize and produce deformities: if left to themselves, they suppurate and produce amyloidosis, or, becoming phagedænic, cause gangrene of the fingers or toes, and septic poisoning.

Complications, in the form of phthisis and amyloidosis, appear, causing fever, cough, and expectoration, diarrhœa, and enlargement of liver and spleen.

Unfortunately, in the midst of disease of almost every organ of the body, the mind is quite clear; but the patients are most irritable, and it is not surprising that, under these circumstances, the patients of a leper asylum require considerable tact in management, and are often peevish and discontented, and that small rebellions occur.

MACULO-ANÆSTHETIC LEPROSY.

In this form of leprosy the infiltration takes place principally into the nerves, with the result that first the fibres are irritated, and later they become destroyed. The first stage is therefore one of irritation of the nerves with such symptoms as shooting-pains down certain nerves, especially the ulnar and the peroneal, accompanied with sensory disturbances, such as burning, numbness, formication, along with vasomotor disturbance—*e.g.*, flushings of the face, glossy skin—and motor disturbance, such as twitching of the muscles, particularly of the face.

Sooner or later a macular eruption appears, which is looked upon by some as due to a lepromatous infiltration of the skin, and by others as nervous in origin. This macular eruption may appear as flat red spots of various shapes and sizes, neither hyperæsthetic nor anæsthetic at first, which appear without fever or any general disturbance of the health. Other maculæ may appear which, instead of being red, are simply pigmented, while still others may be seen in which the pigmentation is less than usual. In any case the spots grow larger, the centres becoming pale, while the peripheries, which are usually raised, and occasionally marked with papules or vesicles, or covered with dry whitish scales, may coalesce with other spots, forming large areas.

The skin in the affected area becomes anæsthetic; the hairs fall out, and wrinkles and scales appear. After a time the areas cease to spread, the raised margin disappears, and the disease becomes quiescent.

Meanwhile the infiltration into the nerve trunks has proceeded to such an extent that a swelling can be easily felt in certain regions —as, for example, in the ulnar behind the internal condyle, in the great auricular over the sterno-mastoid, in the peroneal just below the head of the fibula, and in other nerves in suitable places if affected. With the destruction of the nerve fibres, the hyperæsthetic stage ceases and the anæsthetic stage of the disease begins.

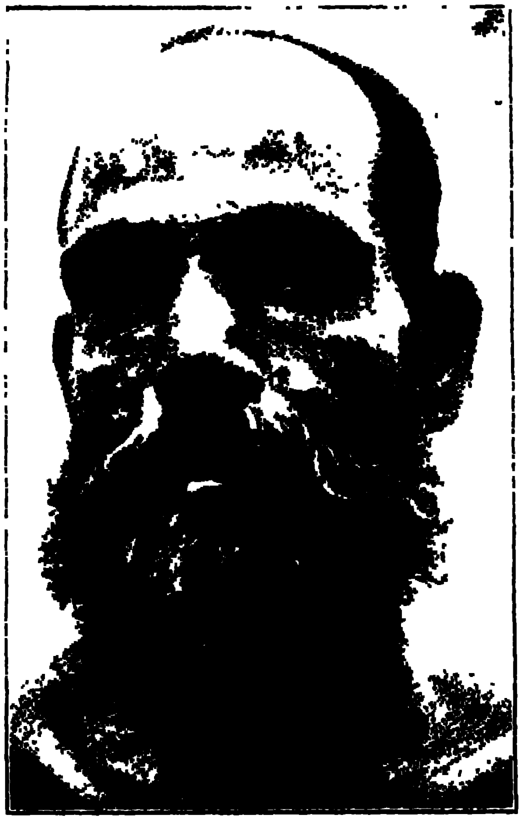

FIG. 731.—MACULO-ANÆSTHETIC LEPROSY: CIRCINATE TYPE.

This is to be noticed along the ulnar side of the hand, forearm, and arm, or on the inner side of the foot, first of all, and afterwards in other places. It may be segmental in arrangement, restricted to the distribution of a nerve, or in patches. At the same time the muscles may be found to be paralyzed, notably the interossei of the hands, but also those of the foot, if carefully looked for. The lower efferent neurones being affected, the symptoms resemble those of muscular atrophy of the Aran-Duchenne type, with the production of the main-en-griffe and the extension of the paralysis to the muscles of the forearm, and even at times, according to Jeanselme, to the deltoid. As a result of the paralysis of the muscles of the forearm the occurrence of dropped wrist is not uncommon.

In the lower limb the plantar muscles of the toes may be affected, while the spread of the paralysis to the peronei and extensors may result in a dropped foot with an internal twist. The reflexes are exaggerated at first, but when paralysis sets in they diminish, and when the muscles waste, the reaction of degeneration may be obtained electrically.

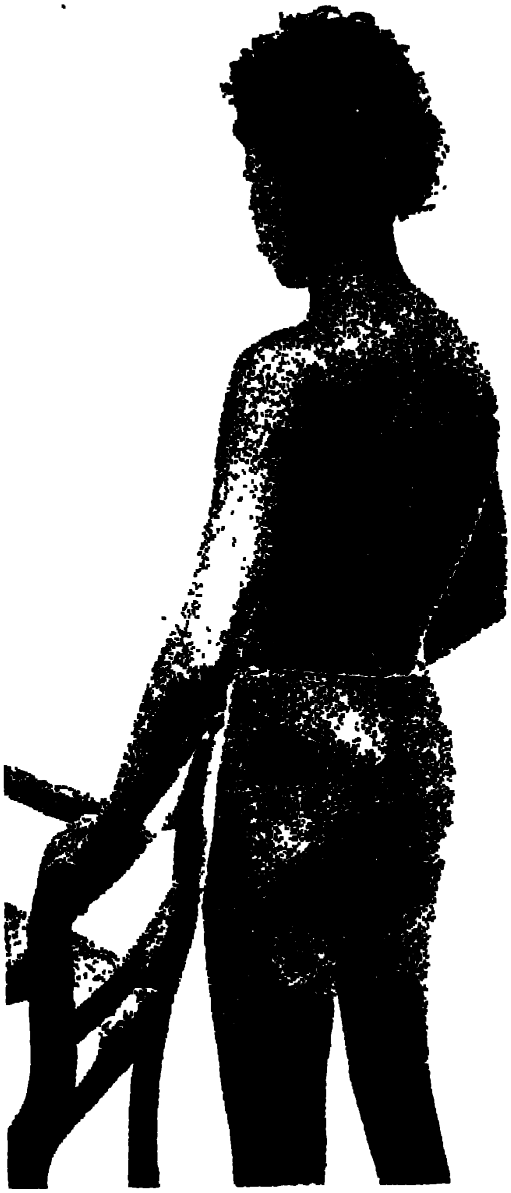

FIG 732.—MACULO-ANÆSTHETIC LEPROSY.

Trophic lesions may also appear in the form of whitlows in the fingers and necrosis of the phalanges, or, instead of this, a simple absorption of the bone of the phalanx or metacarpal, so that the nail may ultimately appear to spring from the metacarpal, the wrist, or even, it has been said, from the elbow. Similar trophic lesions may appear in the foot. Bullæ may appear on the hands or feet, and when broken may form ulcers. Injuries to anæsthetic areas may also result in ulcers, which may be of the perforating type. Fissures may form in the digits, hands, or feet, and, more rarely, dry gangrene may cause loss of the fingers or toes, or greater portions of the limbs, and, still more rarely, the bones of the fingers will soften and become osteomalacic. Trophic lesions of the elbow or knee, like Charcot's joints, have been recorded.

Jeanselme, Bourret, and one of us have studied the cerebrospinal fluid, and have found in a few cases a lymphocytosis, but more usually no cells or bacilli.

The eye is far less commonly affected than in the tubercular variety, Borthen's figures showing that in anæsthetic leprosy no less than 36·83 per cent. of the female cases and 26·80 per cent. of the male cases escape without eye complications. True leprotic lesions are much rarer, the eye being damaged by secondary infections brought about by the absence of the lachrymal secretion and the lagophthalmos. The forehead and supraciliary regions are often reddened and œdematous, but complete madarosis is rare; while paralysis of the frontalis, corrugator supercilii, and orbicularis palpebrarum cause lagophthalmos and ectropion; and as there is a diminution in the secretion of tears, xerophthalmia with posterior or total symblepharon, while desiccation and destruction of the cornea may result.

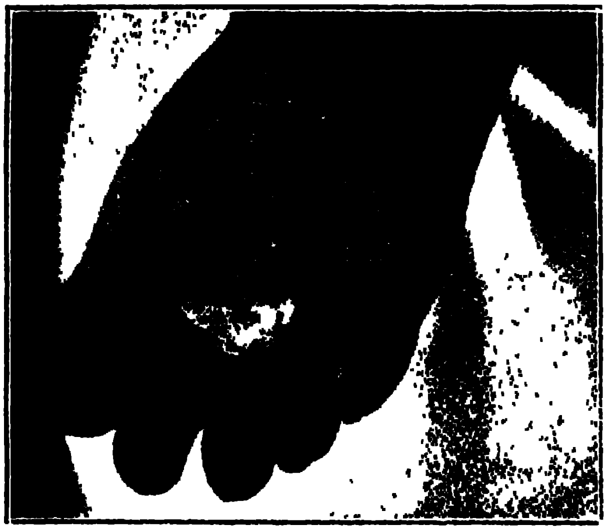

FIG. 733.—LEPROSY: ULCER OF THE FOOT.

Secondary infections may lead to keratitis, onyx, hypopyon, iritis, irido-cyclitis, and destruction of the eye.

Sterility is not so frequent in nerve as in tubercular leprosy. The skin may become infected at an early or late stage of nerve leprosy, thus forming one of the types of mixed leprosy.

Mixed Leprosy.

This term has been used to comprise those cases of tubercular leprosy which develop nerve symptoms, and those of maculo-anæsthetic leprosy which develop nodules, as well as those general cases in which both nerve and skin lesions advance hand in hand.

Paraleprosis.

Zambaco, Von Duhring, Glück, Leboeuf, and others have drawn attention to various phenomena indicating an attenuated infection in regions in which leprosy has long existed. These conditions are mostly nerve or trophic changes—*e.g.*, thickening of the ulnar nerve, the curving of the fingers, the loss of phalanges, the atrophy of the muscles of the hand or face, which are present in the children or grandchildren of lepers. Further, it is believed by some authors that syringomyelia and Morvan's disease may be modified forms of leprosy. Paraleprosis, however, requires further investigation.

Complications.—The important complications of leprosy are nephritis, phthisis, chronic enteritis, and dysentery. Amyloidosis occurs in the internal organs if there is much discharge from ulcerated surfaces. An interesting case of mixed infection—leprosy and syphilis—has been described by Frugoni.

Diagnosis.—The diagnosis of cases of the nodular type is generally easy, and may be readily confirmed bacteriologically by excision of a nodule and microscopical examination of a portion for Hansen's bacillus. The diagnosis of the maculo-anæsthetic cases presents greater difficulties, especially as in most cases the bacteriological examination of excised portions of the patches will give a negative result, though occasionally the examination of the blood taken from the patches or the surrounding zone may show a few mononuclear leucocytes containing bacilli. In these cases the diagnosis must be based on the presence of anæsthesia in the erythematous, non-pigmented, or hyperpigmented patches. Another valuable sign will be, in many cases, the palpable enlargement of the ulnar, peroneal, and other nerves. The search for the lepra bacillus in the nasal mucus is sometimes useful to clear the diagnosis. This method of diagnosis may be facilitated by administering a full dose (30 grains) of iodide of potassium, which often produces nasal catarrh. Sometimes this drug produces a general reaction accompanied by fever, and the appearance of fresh nodules. Leboeuf, acting on Marchoux's suggestion, has found Hansen's bacillus in the enlarged superficial lymphatic glands, and recommends the examination of the gland juice as a method of diagnosis. It is to be noted, however, that this examination will give a positive result much more frequently in nodular cases than in the macular type of the disease.

Chujo recommends drawing 5 c.c. of blood from the arm, diluting it with 200 c.c. of a 3 per cent. solution of acetic acid, avoiding contact with the air.

The microscopical examination would give more than 50 per cent. of positive results.

Some authors recommend the blistering of the skin, and examination of the liquid of the blebs for the presence of Hansen's bacillus. Thompson recommends for diagnostic purposes the injection of pilocarpine, with the view of discovering dry areas in the sweating skin.

Differential Diagnosis.– In countries where leprosy is endemic, other diseases are liable to be mistaken for it. One of the diseases most frequently mistaken, as has been pointed out by Powell and others, is framboesia, which may be recognized by the presence of the *Treponema pertenue* and the framboesiform appearance of the nodules. Leucodermic patches and morphoea are also occasionally mistaken for leprosy, but in such conditions there is no anaesthesia.

Prognosis.—The prognosis is not good. The probability of a permanent cure is slight, but the disease may last a long time. Four to twelve years is laid down for the mixed or tubercular leprosy, and longer for the maculo anaesthetic, and during that time a great deal can be done by appropriate treatment; and, indeed, the disease may be stopped for the time being, only, usually, to recur again. It has been shown by Lie that, even when all the skin eruptions have disappeared, and the patient is only troubled by anaesthesia, and the atrophy of the muscles, and may be thought to be cured, still the bacilli are present in the nerves and spinal cord.

Leboeuf from his recent investigations in New Caledonia has come to the conclusion that in a certain number of cases showing slight symptoms, an actual cure takes place.

Treatment.– So far no specific treatment has been found, though Carrasquilla attempted to prepare a serum by the injection of the blood of lepers into equines, and Abrahams and Hermann by inoculating the juice from lepromata into an animal. These sera have been found useless. Rost prepared a substance, which he called 'leprolin,' on the lines of tuberculin, but, unfortunately, the bacillus he was using was not the leprosy organism. Clegg's vaccine and Bayon's extract of Kedrowsky's strain have not been very successful. Tuberculin has been tried without success, and, in fact, very serious symptoms may follow its injection.

Chaulmoogra Oil.—As regards symptomatic treatment, there is no doubt as to the great value of Chaulmoogra oil, which is said to be obtained by cold expression from the seeds of some species of *Gynocardia* (*vide infra*), but may be adulterated with other oils, especially that of *Hydnocarpus wightiana*, or may be altered by being expressed when heated. It should be rubbed into the diseased patches, and also given internally in doses of 5 to 10 minims, working up gradually to 30 to 60 minims, in capsules, or in a pill with tragacanth and soap, or in an emulsion, or as Engel-antileprol capsules. To remove the after-taste a lime can be sucked. This treatment must be persisted in for a very long time, and should be combined with hot baths, and, in nerve cases, with doses of strychnine, $\frac{1}{60}$ grain three times a day, which may gradually be increased. After a length of time it is as well to make a slight break in the treatment, to prevent toleration, and therefore Unna's ointment of ichthyol, 5 per cent.; salicylic acid, 2 per cent.; and pyrogallol, 5 per cent., or some other ointment, may be temporarily substituted. But the Chaulmoogra oil must not be long discontinued, and must be persisted in for two years or longer if any good is to be obtained.

The oil may be given hypodermically, but is badly absorbed. To facilitate its absorption Heiser has successfully combined it with camphorated oil, and Mercado has combined the mixture with the resorcin formula of Unna. Heiser's present formula is—

Chaulmoogra oil	60 c.c.
Camphorated oil	60 ,,
Resorcin	grms. 4

Mix and dissolve with the aid of heat on a water bath and then filter.

The injections are made in the gluteal region, at weekly intervals, in ascending doses, one to five or ten cubic centimetres. During the treatment the patient takes a hot sodium bicarbonate bath (2 per cent.) every other day. The results are fairly satisfactory. *Sodium Gynocardate.*—Rogers recommends the intravenous injections of sodium gynocardate, which is supplied in sterile vials by Smith, Stanistreet and Co. in doses of $\frac{1}{10}$ grain and upwards. There is a definite reaction, local and general, after the injection. He also gives gynocardic acid and sodium gynocardate orally in 2 grain pills after meals, or by subcutaneous injection.

Neumann has advised the combination of salve and theonin with Chaulmoogra, given either by the mouth or hypodermically, but the advantages are doubtful, and Hollmann has recommended the use of eucalyptus oil in conjunction with opia leaves (*Jambos malaccensis*) or with Chaulmoogra oil.

Sources of Chaulmoogra Oil. According to Ghosh, true Chaulmoogra is *Taractogenes kurzii* from Burma and Assam; false Chaulmoogra is *Gynocardia odorata* from Sikkim, Assam, and Chittagong; other Chaulmoogras are *Asteriastigma macrocarpa*, *Hydnocarpus venenatus*, *H. wightianus*, *H. anthelminticus*. The oil known in Europe as Chaulmoogra is said never to come from *G. odorata*.

Cod-liver Oil and Sodium Morrhuate.—Cod-liver oil is occasionally beneficial. Rogers recommends an intramuscular injection (1 to 3 c.c.) every other day of a 3 per cent. solution of sodium morrhuate.

Other remedies are legion—*e.g.*, X rays have been well spoken of, but must be pushed to the extent of almost burning the patient. A 10-inch spark-coil with a bifocal tube, situate 7 to 10 inches from the lesion, has been used. Hypodermic injections of perchloride of mercury, as advocated by Crocker (0·01 gramme every other day), have been found satisfactory at times—a treatment which we recommend in cases at the very beginning of the disease.

Cashew nuts (Beauperthuy treatment) have been applied to the lepromata with the idea of local caustic action. Thyroid gland, salol, salicylates, arsenic, Gurjun oil, chlorate of potash, iodine, hypodermic injections of iodoform, have all been tried and found wanting.

Hypodermic injections of 'nastin' have been tried. This is a fatty principle extracted by Deycke from cultures of a streptothrix (*Streptothrix leproides*), which he found in the nodules of leprotic patients. The nastin is combined with benzoyl chloride, and made into ampoules with sterilized olive oil by Kolle and Company, of Biebrich, on the Rhine. Each ampoule contains from 0·0005 to 0·0002 gramme of nastin, which is to be injected once a week, and in the small doses produces no local reaction, but in the larger dose causes considerable local inflammation. Deycke's views as to the method of action are that the nastin attaches itself to the lepra bacillus, and then the benzoyl acts on the bacillus, damaging it by removal of its fat, when the normal fluids of the body complete its destruction.

Wise and Minett and others have reported unfavourably on this treatment, but recommend benzoyl chloride in petroleum oil as a valuable nasal spray or paint, as it renders the discharge from the nose free from bacilli.

Castellani and Woolley, and more recently Nicholls, have tried a vaccine prepared by triturating nodules rich in bacilli in salt solution or broth, then filtering through gauze, and finally heating to 60° C. for an hour.

Pasini has tried Finsen light, and Beurmann radium, with good results, and Luque, Moreno, and Padilla have obtained considerable improvement, and it is said cures, by treatment with decoctions of 20 to 60 grammes or 2 to 5 grammes of the powdered mangrove *Rhizophora mangle*, which, given in small doses at first, and gradually increased, are well stood, and produce a gradual improvement in the symptoms; and in the course of a year, it is said, cases may be cured. A. Bertarelli has obtained temporary good results by treating a patient with hypodermic injections of a solution of carbolic acid. Wellman and Rocamara have tried salvarsan, and claim good results. Maxwell has tried Williams' leprolin and Malegin Sprengler's I.K. Lepra with good results. Sugai recommends intravenous injections of a solution of potassium cuprocyanide.

Surgical treatment on the ordinary lines is required for ulcers, whitlows, etc. Eye lesions should be treated as though the disease was non-leprous, and should not be neglected. Grossmann thinks that leprous infiltration might be arrested by the production of cicatricial tissue, by a corneal or pericorneal incision.

With regard to other measures, lepers should be provided with plenty of fresh air and good food, and their quarters should be kept strictly clean. Care should also be taken that they are supplied with some form of light work and amusement, and the institution of rural colonies, provided they are well supervised, is to be recommended.

Prophylaxis.—Beyond isolation and antiseptic precautions after handling leprous people, nothing more can be done, as so little is known about the causation of the disease. The financial burden of isolating large numbers of lepers is very heavy. Hence the difficulty of carrying out this very necessary method of protection completely and efficiently.

CHAPTER LXX

HISTOPLASMOSIS

Definition—History—Ætiology—Pathology—Morbid anatomy—Symptomatology—Treatment—References

Definition. Histoplasmosis is an acute specific infection caused by *Histoplasma capsulatum* Darling (*Cryptococcus capsulatus* Darling).

History.—This disease has been described by Darling, who also found the parasite, but being first discovered post mortem, the clinical signs are rather deficient. The first case was in a negro who, three months previously, had come from Martinique to the Canal zone of Panama.

Ætiology.—The disease is caused by the parasite *Histoplasma capsulatum* Darling, which was at first considered to be a protozoon, but is now believed to be a fungus (*Cryptococcus capsulatus* Darling, p. 1070).

Pathology.—The parasite infects epithelial and endothelial cells of the lungs, liver, and spleen. It also exists free in these organs. In the lungs it gives rise to pseudo-tubercles resembling miliary tubercles.

Morbid Anatomy. In the first case there were ecchymoses and small nodules beneath the visceral pleura of both lungs, which was studded throughout with pale grey hyaline and miliary tubercles, 2 to 3 millimetres in diameter, while the remainder of the organs were of a bright red colour. The peribronchial glands were full of soft caseated tubercles. The heart was small, but normal. The liver was enlarged, pale, and in a condition of slight atrophic cirrhosis. The spleen was enlarged to about three times its usual size, very firm, with distinct Malpighian bodies. The kidneys were slightly cirrhotic; the pancreas, bladder, bone-marrow, and brain were normal, and no tubercle bacilli could be found.

Microscopically the lung tubercles were found to consist of alveoli, the walls of which were broken and collapsed, and were filled with alveolar epithelial cells distended with parasites. In the liver the hepatic cells and the vascular endothelial cells were much infected with parasites. Some areas which stained badly were found to consist simply of the débris of cells with numerous parasites. The spleen showed intracellular and free parasites.

Symptomatology.—The symptoms closely resemble those of Indian kala-azar, there being irregular fever with enlargement of the spleen and liver, and severe anæmia with marked leucopenia.

Treatment.—Nothing is known as to the treatment or prophylaxis.

CHAPTER LXXI

BERI-BERI AND EPIDEMIC DROPSY

Beri-beri—Infantile beri-beri—Epidemic dropsy—Potter's references.

BERI-BERI.

Synonyms.—Polyneuritis Endemica, Neuritis Multiplex Endemica, Hydrops Asthmaticus, Synclonus Beriberia, Myelopathia Tropica Scorbutica, Paraplegia Mephitica, Sero-phthisis Perniciosa Endemica, Panneuritis Endemica, Berbiers, Kakké (signifying a disease of the legs in Japan and China), Loempoe (Java), Kaki lem but, Hinchazon de los Negros y Chinos, Maladie des Sucreries (French Antilles), Hinchazon (Cuba), Inchaçao, or Perneiras (Brazil).

Etymology.—The word 'beri-beri' is said to be derived from the Sinhalese term, meaning 'cannot,' which is used as a phrase, which means 'I cannot,' employed in the sense that the person is too ill to do anything. There is another Sinhalese word which may equally be translated as 'cannot,' but this means that the person is unwilling to do something, not that he is too ill to do it. It is possible that the above interpretation of the word is correct, for Ceylon has long been in the hands of Europeans—*e.g.*, Portuguese, Dutch and English—and therefore a term used therein would be widespread. There is no doubt that the word covered a large number of diseases, from which a definite pathological entity has gradually been separated out. It is to be noted, however, that—at all events, at the present time—the disease does not exist endemically in Ceylon, where there are only imported cases.

Definition.—Beri-beri is an acute or chronic, endemic or epidemic, disease, of unknown causation, which is characterized by degeneration of many peripheral nerves, especially the vagi, the phrenics, and those of the limbs, associated with gastro-intestinal disturbance, cardiac disturbance, and œdema.

History.—According to Scheube, it is possible that the first mention of beri-beri is to be found in the accounts given by Strabo and Pio Cassius of a disease which attacked a Roman army in 24 B.C. in Arabia. Kakké is also mentioned in a Chinese pamphlet belonging to the second century of the present era, and is minutely described in another belonging to the seventh century, while it is recorded as occurring in Japan in the ninth century. In the tenth century a distinction was made between the atrophic, dry, or paralytic, and the hypertrophic, wet, or dropsical forms of the complaint.

In 1758-59 Bontius was the first European doctor to give an account of the disease, which he described under the term 'beri-beri.'

Later, Tulpius, a Dutch physician, also described the symptoms of the disease as seen in a person who had returned to Holland from the Indies. From that time the literature on beri-beri has grown until it has reached enormous proportions, but unfortunately there is no doubt that until recently several diseases, especially ankylostomiasis and epidemic dropsy, were confounded with it. Rogers in 1808, and later Davy, described the disease as 'beri-beria,' while the latter says that it is almost peculiar to Ceylon. There is little doubt that the condition described by Davy was in reality ankylostomiasis.

In 1847 Carter gave a description of the disease, indicating asthma as the principal feature, probably because of the cardiac dyspnœa. In 1873 Fayrer laid great stress on œdema as the important clinical feature. In 1877 Wernich defined the disease kakké in Japan, while van Meedervoort showed that it was the same disease as beri-beri. In 1886 Kynsey published an account of the anæmia or beri-beri of Ceylon, by which he really meant ankylostomiasis: hence the idea that beri-beri was due to *Ancylostoma duodenale*, and hence the large number of cases of so-called beri-beri in Ceylon years ago.

The scientific and clinical study of the disease has been largely due to the work of Oudenhoven, Da Sylva Lima, Overbeck de Rieyer, Baelz, Scheube, Pekelhäring and Winckler, Hamilton Wright, Jataki, Braddon, Fraser and Stanton. The workers on the ætiology of the disease are so numerous that this part of the history is best treated in the section on the causation.

Beri-beri is in certain regions a most serious disease. Thus Braddon says that in the Straits Settlements and Malaya, where the population is only 1,250,000, no less than 150,000 cases of the disease, with 30,000 deaths, have occurred in Government hospitals and infirmaries in the last twenty years: but he says that only one-third of the deaths of Chinese took place in those hospitals, and therefore the total deaths in that period would be about 100,000. It is also a great element in inefficiency, for it is reckoned that 33 per cent. of the sailors of the Japanese Navy prior to 1884 were continuously disabled by it. In 1904-05 it is said that 24 per cent. of the entire sick and wounded in the Japanese armies—*i.e.*, about 85,000 men—were also disabled by it. It is obvious, therefore, that the disease is of great medical and economic interest, for its incidence particularly falls upon the labourer, the sailor, the soldier, and the prisoners in the gaols, and hence hampers both the employer of labour and the Government. Braddon estimates the cost of the disease to the Government of Malaya as £10,000 per annum in direct hospital charges only.

Much work has been done by Eijkman, Vordeman, Fraser, Stanton, Funk, and many other observers, with the result that the consensus of opinion at the present time is that beri-beri is a *deficiency disease*—*i.e.*, is caused by the deficiency of some essential substance in the dietary (*vide* Chapter IV., p. 109).

In 1913 Cooper, and in 1917 Chick and Hume, studied the subject of vitamines, the two latter especially dealing with beri-beri vitamine.

Climatology.—The endemic centre of beri-beri appears to be Eastern Asia, Japan, China, the Philippine Islands, Indo-China, Java, and Malaya. It is also said to occur in Brazil and, according to Plehn, in Réunion, Mauritius, Nossi-bé, Zanzibar, Cape Colony, Senegal, Angola, the Congo Free State, and the Cameroons. We have met with the disease on the Gold Coast in Chinese miners, but have not noted it in the native population, though it may possibly exist. Isolated epidemics, sporadic or imported cases, occur in England, Ireland, and other parts of Europe, the United States, Canada, and in Ceylon. In the last-named place it is now almost entirely absent, and, indeed, it is possible that many of the cases reported years ago may have been ankylostomiasis or some other disease. Imported cases from India and China are frequently met with in Colombo, owing to its possessing a large harbour where numerous vessels, with Chinese and Indian crews, call.

It is believed that the Bihimbo disease of the Chaka district of Uganda is beri-beri. The disease known in that country as munhiyo, and believed at one time to be beri-beri, has been demonstrated to be Malta fever. In the tropics it is said to occur more often in the cool wet months.

Ætiology.—The causation of beri-beri is at the present time believed to be due to the deficiency of some essential substance in the food, but as may be imagined in such a widespread and fatal disorder, the investigators have been many, and hence the theories are legion. In order to comprehend the present state of the question, it is necessary very briefly to review a few of these theories, which will be best done by following a method of classification.

A. Physical Cause.—The older writers, like Davy, considered that it was brought about by some unusual state of the atmosphere, but they said, honestly, that this was merely a cloak for their ignorance of the true cause.

B. Chemical Causes.—The chemical causes which have been advanced are:—

1. Arsenical poisoning (Ross).
2. Oxalate poisoning (Treutlein).
3. Carbon dioxide poisoning (Ashmead).
4. Food poisoning:—
   (*a*) Ichthyotoxismus (Grimm and Miura).
   (*b*) Sitotoxismus (Eijkman, Vorderman, Yamagiwa, Van Dieren); rice (Gelpke, Braddon); lathyrism (Le Roy de Méricourt).
5. Some deficiency in the food:—
   (*a*) Deficient nitrogenous complex (vitamine) (Eijkman Fraser, and Stanton).
   (*b*) Deficient nitrogen (Takaki).
   (*c*) Deficient fat (Brémaud and Laurent).
   (*d*) Deficient vegetables, together with an infection (Fales).
   (*e*) Deficient phosphorus.
   (*f*) Deficient cholesterin (Chrisostem)
6. An intoxication from a germ living outside the body (Manson).
7. An intoxication or an auto-intoxication (Duerck).

1. **Arsenical Poisoning.**—R. Ross, in 1900 and subsequent years, drew attention to the similarity between beri-beri and the arsenical poisoning which at that time was prevalent throughout Lancashire, being brought about through the agency of arsenical beer. He further supported this by finding arsenic in the hair in recent, but not in old, cases of the disease in Penang, and woke up a controversy as to whether arsenic existed in normal hair or not. But apart from the obvious reasons against this theory as an explanation for such a widespread disease, Herzog has definitely shown that no arsenic could be found in the hair of ten cases of different types of the disease. There is no doubt that cases of chronic arsenical poisoning do occur in the tropics, as we have seen, particularly in Europeans who have had to live for a long time on tinned food, but these cases are not beri-beri.

2. **Oxalate Poisoning.**—The oxalate theory is based upon the fact that Maurer and Treutlein were able to produce a condition resembling beri-beri in fowls by giving them oxalic acid in their food. The latter observer considered that the acid removed the calcium salts from the body of these animals, and caused thereby a degeneration of the peripheral nerves and heart muscle, and considered that this was proved by curing them by the administration of calcium salts. Further, he showed that there was an excessive excretion of calcium in the urine of beri-beri patients. But polyneuritis has been produced in fowls by Eijkman by feeding them with cooked rice, and it is possible that neither oxalic acid nor rice, but an infection, was the cause of the disease, which may, of course, be quite different from true beri-beri.

3. **Carbon Dioxide Poisoning.**—Ashmead believes that the disease is caused by the excessive inhalation of carbon dioxide, but outbreaks occur without any overcrowding, as we have seen ourselves.

4. **Food Poisoning.**—(*a*) *Ichthyotoxismus.*—Grimm considers the ingestion of raw fish to be the cause of the disease, and Miura the consumption of species of the Scombridæ; but Wright has shown that in the gaol at Kwala Lumpur, the disease infected forty-nine prisoners when no fish had been given for eight months.

(*b*) *Sitotoxismus.*—Rice poisoning at present is the favourite theory, and has had many supporters. Thus Eijkman and Vorderman consider that it is due to eating rice without husk, which is the natural protection. Gelpke considers that it is due to stale or badly-kept rice. Yamagiwa considers it due to rice improperly stored and preserved, as it occurs even when this rice is well boiled. Braddon, who is often wrongly quoted, ascribes the disease to the ingestion of a *poison* found in the rice, which is the result of the specific product of some organism—epiphyte or parasite—but he does not believe that the disease is due to the ingestion of the organism. Contrary to Eijkman and Vorderman, Braddon looks upon the husk as the dangerous element, as it is in this that the germ grows.

But the disease has been observed, according to Scheube, who quotes Fiebig and Voorthuis, in Brazil, the Moluccas and Lingga, where the people live on sago, fish, and game, and where the attacked Europeans had never eaten rice.

Travers details an interesting observation on this point concerning an epidemic of beri-beri in the Pudoh Gaol of Kwala Lumpur, in August, 1895, when some of the cases were transferred to the Old Gaol, one and a half miles distant, on October 1, 1895, because the mortality in the Pudoh Gaol was extremely high; and on October 25, 1805, sixty prisoners, showing no signs of the disease, and apparently in good health, were similarly transferred. From October 1 to December 14, 1895, all food supplied to the healthy prisoners in the Old Gaol, as well as to the beri-beri patients transferred from the Pudoh Gaol, was cooked in the Pudoh Gaol with the food for the other prisoners who were suffering from the disease.

This food was carried to the Old Gaol twice daily, and the diet was exactly the same in both gaols, the rice being taken out of the same bag and cooked in the same steamer. Further, it appears from Braddon's remarks that in 1895 a new scale of ordinary diets, with an increased amount of rice, was allowed, fresh fish was replaced by salted, and beans were omitted, and

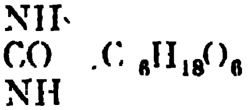
Braddon considers that it was this increase of the rice that increased the poison and made people ill; but this ought to apply to both places.

Moreover, Braddon considers deductions adverse to rice in the above experiment to be fallacious, for he holds that the length of period of incarceration of the above prisoners is an important factor; for the liability to acquire the disease, he says, increases with and varies directly according to the length of the time served in prison, which must be more than six months. He points out that it is not stated how many long-sentence prisoners were sent to the Old Gaol, which he thinks may not have been more than two or three; and concerning these, he says, there is no proof that any of them were kept for the period necessary to acquire the disease by rice intoxication. He therefore concludes that Travers' experience affords no ground for opposing the theory that beri-beri is incurred through the consumption of certain sorts of rice.

5. SOME DEFICIENCY IN THE FOOD—(a) *Deficiency of Certain Nitrogenous Complexes.* There is a growing tendency to consider that certain diseases—*e.g.*, beri-beri polyneuritis of birds, epidemic dropsy, scurvy, experimental scurvy, infantile scurvy, and ship beri-beri—are diseases due to the deficiency in some essential substance in the food. These diseases Funk classifies together as 'deficiency disease,' and characterizes them by certain general symptoms—*e.g.*, (1) Cachexia, with great loss of weight; (2) marked nervous symptoms, generally of the nature of peripheral neuritis. He divides these diseases into two groups—the beri-beri group comprising beri-beri, polyneuritis in birds, and epidemic dropsy; and the scurvy group.

With regard to beri-beri, as already pointed out, Braddon drew attention to the importance of rice as an ætiological factor. Eijkman in 1897 had shown that it could be prevented and cured by the use of hand-milled rice. Prisoners fed upon red rice escaped, and those on white rice were very prone to take the disease. Fraser and Stanton showed that members of gangs of coolies, who had previously remained quite healthy, developed beri-beri when fed on white rice, while other members fed on brown rice remained healthy. Strong and Crowell observed that in eight out of seventeen prisoners fed on white rice, symptoms of beri-beri appeared in from 61 to 75 days. The difference between these two forms of rice is that the white rice is deprived of its subpericarpal layers (*vide* pp. 104 and 105) by the process of milling.

These layers contain a substance called by Funk beri-beri vitamine, which is probably a base belonging to the pyramidine group, and has the formula—



$$\left.\begin{matrix}NH\\CO\\NH\end{matrix}\right.\,.C_6H_{18}O_6$$

and not $C_{17}H_{18}O_4N(HNO_3)$, as previously stated. This substance is soluble in water, alcohol, and acidulated alcohol, is dialyzable, and can be destroyed by heating to 130° C. It is present in the proportion of 0·1 gramme to the kilogramme of rice. According to Funk, this substance is essential for the metabolism of nervous tissue; and if it is not present in the dietary, must be supplied by the animal body, and if this fails, the nervous tissues begin to break down, and as a result the signs and symptoms of beri-beri appear.

Fraser and Stanton believe that the phosphorus content of the rice is a good index as to whether it is harmless or harmful. A safe rice yields more than 0·4 per cent. of phosphorus pentoxide, while a dangerous rice yields less than this figure. Chamberlain and Vedder have suggested that potassium should be used instead of phosphorus for standardization purposes.

With regard to these findings there is an almost unanimous support from all sides, but the Philippine investigators, while believing that their studies support the polished rice theory, bring forward the curious fact that beri-beri began to diminish among their Native Scouts during the last half year of 1910 without any decrease in the general incidence of the disease in the islands, and *four months before the use of under-milled rice was introduced into the dietary*. They consider that the reduction was either due to unknown causes acting coincidentally with a reduction in the amount of rice in the dietary, together with the addition of a legume, or was due directly to these dietetic changes.

Eijkman, Braddon, Fraser, Stanton, Vedder, and Chamberlain have done sufficient work to make imperative the use of brown rice cooked in ordinary vessels, and the exclusion of the white rice as a staple article of food.

Edie, Evans, Moore, Simpson, and Webster have separated an antineuritic base called 'torulin'– $N(CH_3)_2C_4H_7O_2(HNO_3)$– from yeast, and Thomson and Simpson have noted rapid recovery of patients placed on a full diet, and given 1 ounce of yeast and 200 grammes of katjangido-beans daily.

Heiser reports that after being present for five years in the Culion Leper Colony in the Philippines, beri-beri disappeared in nine months on a dietary of unpolished rice.

In 1917 Chick and Hume showed that in order to keep a man in health there must be (*a*) a suitably proportioned supply of protein, fat, carbohydrate, salts, and water; (*b*) an adequate amount of vitamines; and that these two factors could not replace one another. The vitamines of importance in beri-beri they call 'antineuritic or anti-beri-beri,' as the first term covers the polyneuritis in fowls. Neither vitamine has yet been isolated in a pure condition. Pigeons deprived of anti-beri-beri vitamine develop acute polyneuritis in fifteen to twenty-five days. The principal source of this vitamine is the seeds of cereals and pulses. In the former it is mainly deposited in the germ or embryo of the grain and to a less extent in the grain. It is also found in eggs and yeast. It can withstand drying and also temperatures of 100° C., but is destroyed at 120° C. The deduction is that, in order to prevent beri-beri, bread and biscuit should be made from the germ-containing or wholemeal flour. Antineuritic vitamines cannot be expected to survive in tinned or sterilized foods; hence the necessity in armies to supply vitamine from other sources.

The deficiency theory in some form is at the present time accepted all over the world, but there are still some observers who think that there may be more than one form of disease concealed under the name beri-beri.

The following objections have been raised against the food theory:—

(1) Beri-beri may occur in people who do not feed on rice. We have seen an epidemic among officers on a man-of-war.
(2) The geographical distribution. In populations eating the same kind of rice some suffer from beri-beri and others do not.
(3) Tamil coolies in Ceylon do not get beri-beri, though they suffer from this disease in the Straits Settlements. In both countries they are mostly supplied with the same kind of rice (Rangoon rice).
(4) People recovered from beri-beri go back to their usual rice diet without again suffering from the disease. Thus in the Malay States the mortality is only 20 per cent.; therefore 80 per cent. of sufferers recover. Do these people change their diet?

Fraga, having failed to produce beri-beri in prisoners fed on polished rice, believes that dietary deficiency acts merely as a predisposing cause.

(*b*) *Deficient Nitrogen.*—Previous to 1884, 33 per cent. of the sailors in the Japanese Navy were disabled owing to beri-beri.

In 1883 the *Ryujo*, a Japanese warship, went on a voyage of 271 days to New Zealand and South America, and developed 160 cases of the disease out of a crew of 350 men. Takaki investigated this outbreak, and came to the conclusion that there was too little nitrogen in the diet, the nutritive value of which was: Proteids, 109·29 grammes; fats, 15·8 grammes; carbohydrates, 622·32 grammes. He therefore changed the diet to: proteids, 196 grammes; fats, 43 grammes; and carbohydrates, 775 grammes; and on this dietary the warship *Tsukuba* was sent the same cruise, taking 287 days, and only suffered from sixteen cases of the disease. Takaki attributed the success to the increased nitrogen, a portion of the rice being replaced by corn or bread; but Fales has pointed out that fresh vegetables were increased from 215 grammes to 450 grammes, and that therefore nitrogen alone may not have been the cause of the decrease of the disease. This dietary was applied to the Japanese Army and Navy, and beri-beri decreased enormously. But Baelz has pointed out that this decrease was associated with a great improvement in general hygiene and that it also took place in barracks in which the food had not been changed. A similar decrease in the Dutch-Indian Navy, associated with a better diet, was attributed by some to the improved hygiene rather than to the diet.

(*c*) *Deficient Fat.*—Brémaud and Laurent believe that the disease is due to too little fat in the food, and consider that an epidemic at Chandabun, in Siam, was stopped by causing fat to be more freely consumed by the healthy. This theory, however, has found but little support.

(*d*) *Deficient Vegetables, together with an Infection.*—Fales, from a study of an outbreak of an epidemic of beri-beri in the Bilibid Prison, in Manila, came to the conclusion that the lack of fresh vegetables conduced powerfully to both beri-beri and scurvy.

In November, 1901, there were two cases of the disease, and no deaths, in that gaol. The food was then changed to a ration consisting of 97·17 grammes of proteids, 17·24 grammes of fats, 491·04 grammes of carbohydrates, and 26·52 grammes of salts. In this diet there were 85·05 grammes of potatoes, and 453·60 grammes of rice. Put into other figures, this diet consisted of: Nitrogen, 172·1 grammes; carbon, 4,166·5 grammes; hydrogen, 61·9 grammes; sulphur, 13·2 grammes; salts, 140·2 grammes—the proportion of nitrogen to carbon being as 1 to 24·2. Whereas, calculating the weight of Filipinos at 125 pounds, it was estimated that proteids ought, according to Voigt's diet, to have been at least 94 grammes, fats 45 grammes, and carbohydrates 400 grammes; or, according to Moleschott's diet, nitrogen 256 grammes; carbon, 3,789 grammes; hydrogen, 143 grammes, sulphur, 23 grammes; salts, 172 grammes—*i.e.*, N : C :: 1 : 0·15.

The epidemic of beri-beri now began: December, 1901, 52 cases and 2 deaths; January, 1902, 169 and 12; February, 1,087 and 16; March, 576 and 15; April, 327 and 15; May, 310 and 19; June, 451 and 17; July, 233 and 33; August, 571 and 24; September, 522 and 31.

On October 20 the diet was again changed, and this time proteids were 101·71 grammes; fats, 19·37 grammes; carbohydrates, 395·73 grammes; salts, 29·13 grammes; including 119·07 grammes of potatoes and 255·15 grammes of rice. Nitrogen was 209·8 grammes; carbon, 3,816·2 grammes; hydrogen, 70·4 grammes; sulphur, 17·2 grammes; and salts, 185 grammes—N : C :: 1 : 13·4.

In October there were 579 cases and 34 deaths; November, 476 and 8; December, 89 and 3; half January, 1903, 4 cases and no deaths.

Along with the beri-beri there was an epidemic of scurvy, and Fales was of the opinion that both diseases were led up to by a deficiency of vegetables, the essential principle of which he believes to be potassium carbonate, of which rice contains only 0·01 grain per ounce, while potatoes contain 1·875 grains. Hence, according to Fales, the disappearance of the disease when a sufficiency of vegetables, especially potatoes, was given. But he says this deficiency was only a predisposing cause, which enables the micro-organism, whatever it is, which is the true cause of the disease, to flourish and produce the symptoms. In other words, the people get run down by a bad diet, and are ready for any disease, so that this does not clear up the ætiology.

Recently Ingram has drawn attention to an outbreak in the 81st Pioneers and the 2nd Battalion of the King's Own Scottish Borderers, at Aden, in which he could find no clear evidence that beri-beri was due to diet alone, whether insufficient proteids or excessive rice, or bad rice, but he considered a diet rich in proteids good as a preventative. He could only find one thing in common in the two regiments—viz., both brought the disease with them—but was unable to find any source of infection, parasitic or otherwise.

(*e*) *Deficient Phosphorus.*—Schaumann and [illegible] have maintained that deficient organically combined [illegible]rus in the u[illegible]ed rice is the ætiological factor.

(*f*) *Deficient Cholesterin.*—Ch[illegible] has treated [illegible]s with injections of cerebrin with good results, and with 5 p[illegible]ent. cho[illegible]rin in olive oil with better results.

6. An Intoxication from a Germ living Outside the Body.—Manson brought forward the hypothesis that a germ may live in the soil, the house, or the ship occupied by the human being, under certain conditions of temperature and moisture, and may grow and produce some kind of toxin which, being inhaled or swallowed, or otherwise introduced, causes the disease. Moreover, this germ may be carried by men from place to place.

He supports this theory by pointing out—(1) that when patients are removed from an endemic spot they at once begin to rec[illegible] (2) he quotes Hirota's observation that fifty-two infants nursed by beri-beric mothers showed signs of the disease, and did not improve wh[illegible] treated medicinally, but rapidly improved, if th[illegible] had not advanced too far, when taken from these mothers and placed on artificial food or given to a healthy wet-nurse. Further, Herzog says that, according to Dr. Albert, similar cases are not very infrequent in the Philippine Islands, but the removal of the child from the mother is most difficult, as the people do not understand the necessity.

Manson rightly points out that these children must have been poisoned with some chemical substance, and not infected with a germ. But, of course, the germ causing the toxin might be in the mother's body.

Again, Manson points out that the disease clings to ships, in which it appears year after year when the tropics are reached. There is also evidence that the cause, whatever it is, clings to rooms for a short time.

7. An Intoxication or an Auto-Intoxication.—Duerck is convinced from the study of the pathology that the cause of the disease is a toxæmia, and points out that substances formed in the body by process of auto-

intoxication may produce peripheral neuritis, but the epidemics of the disease are quite against a theory of auto-intoxication.

C. Parasitic Causes.—A great many observers are in favour of a parasitic cause for the disease, without committing themselves as to whether it is animal or vegetal. Among these may be mentioned Sambon, who considers that the specific agent lives in the patient's body. Scheube considers that it is an infectious, but not a contagious, disease, and says that the analogy with malaria is in some respects striking, and that it is spread by mechanical transmission of the disease by human intercourse in some way or another. This is quite true, because there are numerous instances of disease being imported by human beings into a fresh place and spreading, but the curious point is that it generally sticks to one race.

Thus, in Malaya it is a common disease among imported Chinese, and hardly known among the natives. In the Bilibid Prison, mentioned above, the prisoners included Filipinos, Spaniards, Chinese, Japanese, Indians, American negroes, Americans, and Europeans, but the disease fell most severely on the Filipinos, the Chinese being almost exempt, only one or two contracting the disease, while the Americans were immune. Van der Scheer suggested that perhaps insects, such as cockroaches, might be the spreaders of the disease, but Durham's investigations are contrary to this. It would seem as though the causal agent was spread by some parasite, for Daniels has carefully considered the question of infection, and does not find any evidence in favour of it being conveyed by the excreta of persons suffering from the disease, especially the

Further, he points out that infection by air and water can be excluded, as in Kwala Lumpur all races drink the same water, but only Chinese are attacked, even though they drink little unl [illegible] water: and the immunity of prison officials from the disease while [illegible] pidemic rages among the prisoners excludes air. Disinfection appears, from Durham's results on Christmas Island, to be useless. As regards parasites Durham and Daniels are both against mosquitoes as being the cause—and, indeed, this is hardly likely—and also against bugs.

On the other hand, there appears to be some evidence in favour of *Pediculus capitis*, which is apt to cling to one race, and this is, according to Daniels, a plausible theory in explaining the racial selection of the disease. Experiments on an orang outang with pediculi from a beri beri case were negative, the lice rapidly disappearing. Daniels could not exclude fomites as a carrier of the disease in his observations. Only one observer, Taylor, is said to have produced the disease in animals by the inoculation of the blood from patients.

Having thus briefly considered the general question of contagium vivum, and its method of entry into the body, it is necessary to review the various organisms which have been held to be the cause of the disease.

They may be classified into:—

ANIMAL PARASITES:—

(*a*) *Protozoa.*

1. Plasmodium in the blood (Glogner).
2. Protozoon in the urine (Hewlett and Korte).
3. Hæmatozoa in the blood (Fajardo and Voorthuis).

(*b*) *Nemathelminthes.*

1. Some form of *Trichinella* (Gelpke).
2. *Trichuris trichiura* (Erni and Kynsey).
3. *Ancylostoma duodenale* (Erni and Kynsey).

VEGETAL PARASITES—FUNGI:—

(*a*) *Coccaceæ.*

1. Cocci in the alimentary canal, etc. (Dangerfield).
2. Diplococcus in the urine (Tsuzuki).
3. Diplococcus from the blood and urine or organs post mortem (Okata and Kokubo).
4. Four kinds of cocci (Musso and Morelli).

(*b*) *Coccus and Bacillus.*

Pleomorphic organism obtained by Pekelharing and Winckler from the blood.
Bacilli and cocci by Lacerda.

(*c*) *Bacilli.*

1. Bacillus by Taylor.
2. Bacillus by Rost.
3. Bacillus by Ogata.
4. Three kinds of bacilli by Nepveu.
5. Bacillus by Eecke.

Toxins from a bacillus in the alimentary canal (Hamilton Wright).

(*d*) *Fungi higher than Bacteria.*

Mouldy rice (Hose).

Protozoa.—Glogner's parasites were similar to malarial parasites, but were distinguished therefrom by being found only in splenic blood, by being always extracorpuscular, and by increasing by gemmation. They were more pigmented than malarial parasites. Scheube thinks that Glogner's cases were complications of beri-beri with malaria.

Hewlett and Korté centrifugalized the urine of beri-beri cases, and found small retractile spherical bodies, 2 to 3 μ in diameter, with a thick capsule and hyaline contents; others 20 μ in diameter, with a cytoplasm studded with retractile granules, and containing a single nucleus; and others 30 μ, with a thick capsule, an oval nucleus, and a rounded nucleolus. They further described the congestion of the glomerular vessels and hæmorrhages into the tubules of the kidney. Further, they saw a somewhat similar disease in monkeys, the urine of which contained highly refracted cells. They conclude that the above are either peculiar degenerate cells or protozoa, and suggest that the disease is a protozoan infection, and that the causal agent is eliminated by the urine. Fijordo and Voorthuis separately describe hæmatozoa, partly free and partly in the red cells, which are similar to, but not identical with, the malarial parasites. Their organisms do not agree with one another, nor do they correspond to Glogner's.

Nemathelminthes.—Gelpke suggested that the disease might be due to a *Trichinella* in fish, but he has withdrawn this. *Trichuris* and *Ancylostoma* need not seriously be considered, as this idea arose from a misunderstanding.

Fungi.—Pekelharing and Winckler's bacillus has also been found by Hunter, and experimental inoculations by both sets of observers produced degenerations of the nerves. But it must be admitted with regard to bacteria that competent observers have found the blood sterile time after time.

Hamilton Wright's bacillus, which occurs in the alimentary canal, has been found by Dudgeon to be non-pathogenic for monkeys, and not to be agglutinated by the blood of beri-beri patients. Stanley's experiments on animals with mouldy rice have been negative. Finally, attention may be drawn to the researches of Holst, Nocht, and the Norwegian Ship Beri-Beri Committee, which indicate that the so-called ship beri-beri is not beri-beri, as the symptoms are shortness of breath and weak heart, with weakness and dropsy of the lower limbs, but not paralysis of the limbs—*i.e.*, the degeneration of the nerves is not an essential phenomenon.

Chalmers and Archibald separately have found fungi in the organs of cases of beri-beri occurring at different times in British troops in Khartoum. We feel that more than one disease is included under the term beri-beri. One of these diseases is a ***deficiency disease***, but the others await discovery.

Predisposing Causes.—The disease can occur in all races, and at all ages, and in both sexes, but it is apt to cling particularly to one race in a country—*e.g.*, the Chinese in Malaya, the Filipinos in the

Philippine gaol outbreak. This racial incidence is most marked. Thus, Braddon says that of the Chinese immigrants into the Straits and Malaya, it may be reckoned that of every 1,000 living, 120 suffer and 16 die of the disease. The Malayas are said to suffer but little, if at all. In the Bilibid Prison in Manila, on the other hand, according to Fales, the Filipinos suffered most severely, the Chinese were almost exempt, only one or two contracting the disease, while the Americans were entirely free.

With regard to age, it is most commonly met with in young adults between fifteen and thirty years, but it has also been noted in babies at the breast and in old men. It is more commonly met with in men than in women.

Occupation has been carefully investigated by Hunter and Koch in Hong-Kong, and they conclude that the disease is universally present throughout the community, but especially affects the working classes, while the professions, the merchants, and the leisured classes are practically, but not entirely, exempt. Other predisposing causes are disturbance of the soil and a high atmospheric temperature.

Important Features. The peculiar features of the disease are that, though it generally occurs among rice-eating peoples, yet at times it occurs in other communities, as in the British regiment, in whose ration there was but a small quantity of rice, which was cured Rangoon rice. Finally, if observers are to be trusted, there are places where beri-beri occurs and rice is not eaten.

Pathology. As the cause of the disease is unknown, but little can be said as to the pathology, but Mott and Halliburton have performed an experiment which throws much light on the disease. They injected blood taken from an acute case of beri-beri into a cat, and found a fall of blood-pressure, with dilatation of the vessels of the stomach, intestines, and liver, as well as general venous engorgement, and they also noted dilatation of the right side of the heart, and microscopical hæmorrhages into the liver. This would clearly indicate that a poison capable of producing great vasomotor changes was circulating in the blood of beri-beri patients. In addition to the engorgements found in the cat, the human being suffers from congestion of the pharynx, and degeneration of the cardiac, muscular, and sensory nerves. The œdema is probably due to the vasomotor disturbance.

Durham considers that the urine indicates a serious diminution of the metabolism.

Morbid Anatomy.—The morbid anatomy and histopathology have been studied by numerous observers, among whom the investigations of Wright, Duerck, and Scheube must be especially mentioned. In acute cases there is always some œdema, but at times this may be excessive, and the veins of the neck are swollen. Hypostasis is always well marked, but may be excessive, especially about the face. There is often froth at the mouth. In chronic cases the body is pale, and may be swollen with dropsy or emaciated.

In the former the post-mortem rigidity develops quickly, and is well marked. In the latter, however, it is not so marked. On cutting into the body the subcutaneous tissues are usually œdematous, and the veins are filled with dark fluid blood. There is a varying quantity of serous fluid in the abdomen, the chest, and the pericardium, and there may be petechial hæmorrhages under the visceral pleura and pericardium in acute, but not in chronic, cases. The throat and tonsils are generally congested in acute cases, but they may be normal; the larynx may be congested or normal. The mucosa of the trachea and bronchi may be œdematous, with the lumen full of fluid. The lungs may be congested and œdematous, and may contain little air.

The right side of the heart is always greatly dilated in acute cases, and is also hypertrophied in older cases, but it is rare for the left ventricle to be hypertrophied, though it may be dilated to a moderate extent. The myocardium generally shows fatty degeneration, the striation is often absent, and segmentation and vacuolation of the fibres, with an increase of the interstitial tissue, can also be seen, and there is a round-celled infiltration beneath both endo- and epi-cardium in acute cases. (These changes are said by Scheube to be like those found in rabbits after section of both vagi.)

According to Wright, the entire nervous system of the heart is damaged in acute cases, the cells of the bulbar nuclei and the nucleus ambiguus on both sides being swollen, with excentrically placed nuclei and a disappearance of Nissl's bodies in the processes, and to a less extent at the periphery. These changes may also be seen in the first and second pair of the thoracic ganglia, and in the intrinsic ganglionic cells of the heart, while the vagal nerve-endings show rounded droplets of altered myelin (neurokeratin?), especially near the nodes. In chronic cases only the vagi may show degeneration, the ganglia in the heart being normal.

In acute cases the stomach and duodenum are markedly affected, the mucosa being hyperæmic, with more or less marked hæmorrhagic extravasations, and even at times effusion of blood into the lumen of the viscus. This inflammation may extend to the ileum, or very rarely even to the cæcum, but usually the small and large intestines show nothing abnormal, for the acute irritation is located to the pylorus and the duodenum.

Microscopically there is an acute congestion with round-celled infiltration, with, according to Herzog, a very large number of eosinophile cells and necrosis of the glandular epithelium. The cells of Auerbach and Meissner's plexuses are degenerate, and the nerve fibres in the stomach and duodenum also show signs of degeneration. In chronic beri-beri these gastro-duodenal signs are absent.

In an acute case the lymphatic glands near the stomach and duodenum are enlarged and congested. The liver is generally enlarged and congested, and at times in a nutmeg-like condition, and, according to Hewlett and Korté, there may be extensive hæmorrhagic patches. Scheube and Plehn draw attention to a round-celled infiltration of the interlobular connective tissue, which the latter calls a beri-beric interstitial hepatitis. The cells show fatty degeneration, cloudy swelling, and at times necrosis. The spleen may show some cyanosis, and be slightly enlarged and indurated, but usually it is normal. The wall of the gall-bladder may be œdematous at times; the pancreas is normal. The suprarenals may be pigmented and congested with vacuolated cells. The kidneys are usually swollen and hyperæmic, and there may be hæmorrhages into the glomeruli, tubules, and pelvis, together with cloudy swelling and cellular infiltration. The ureters and bladder are usually normal.

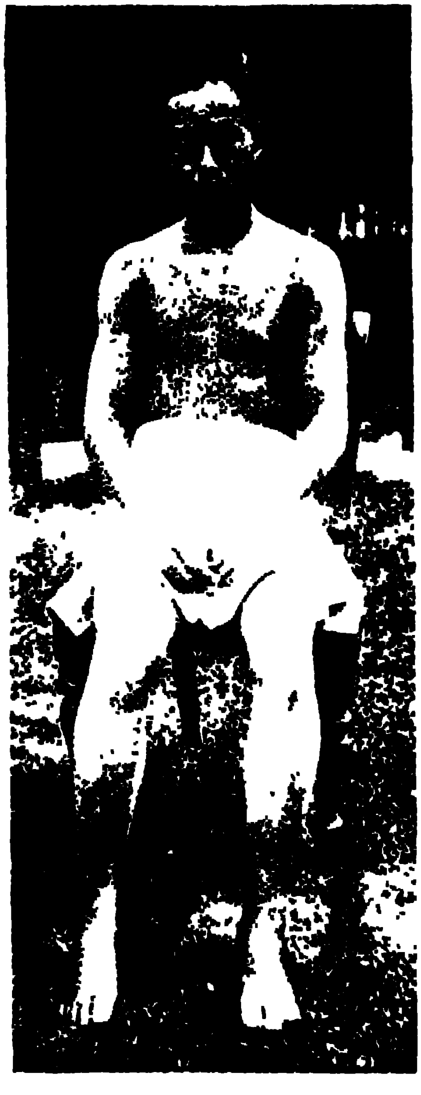


FIG. 734.—BERI-BERI: DROPSICAL OR HYPERTROPHIC FORM

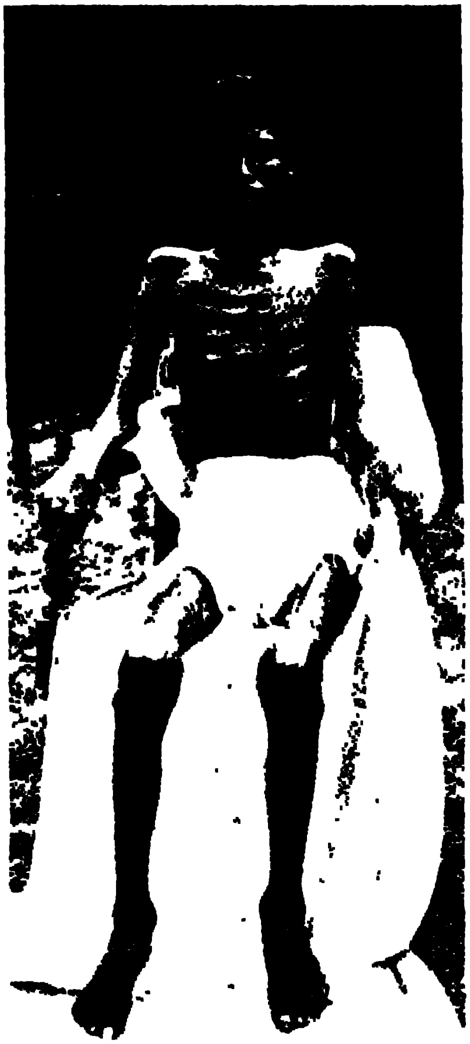

FIG. 735.—BERI-BERI: DRY OR ATROPHIC FORM

The nervous system is markedly affected. The meninges of the brain may be hyperæmic, and there may be some hyperæmia of the brain substance itself, and increase of fluid in the ventricles, but the microscope shows nothing abnormal except in the bulb, where, according to Wright, there are the changes already mentioned in the vagal nucleus. Kustermann also describes acute degeneration of the vagal ganglia at the base of the fourth ventricle.

The spinal cord is usually normal. Hamilton Wright and others have described degeneration of the cells of the posterior spinal ganglia and anterior cornua of the lumbar cord, together with atrophy of Goll's column, in which histologically there is a thickening of the glia tissue and a complete disappearance of the nerve fibres, with the presence of many granular cells.

The peripheral nerves are usually normal to the naked eye, but may be injected and hæmorrhagic. Scheube and Baelz first showed that these nerves were degenerated, the muscular branches of the nerves of the limbs being most affected, but even the fine sensory cutaneous branches were also attacked. The changes in the autonomic nervous system do not appear to have been closely studied, though several observers have recorded changes in the ganglia, and in the cardiac and other plexuses.

The degeneration of the nerve fibres has been carefully studied by Scheube, Baelz, Hamilton Wright, and Duerck. The neurokeratin network becomes irregular, and its meshes wider, while its rods disappear. The medullary sheath becomes vacuolated, and its inner boundary ill-defined. In other places the neurokeratin network condenses into small rosary-like masses or larger lumps, somewhat regularly arranged. Later the medullary sheath breaks up into spherical or elongated masses separated by clear intervals. The axone undergoes first chemical changes, and then appears like a wavy cord, or as a series of comma-like segments, or twisted up into a coil. Finally, both axone and medullary sheath disappear, while Schwann's sheath collapses, and so the nerve fibres become lost in the connective tissue of the endoneurium. Along with these changes there is a cellular infiltration of the perineurium, especially of the perivascular spaces, and also of the endoneurium. These cells are said to be like a similar infiltration met with in traumatic lesions of nerves, and to resemble the granule cells of the central nervous system. When fully degenerated, the nerve may consist simply of connective tissue. Regeneration has not been observed, but must occur—at all events, to some extent—in cases which recover.

The muscles show atrophied and normal fibres side by side. The diseased fibre first loses its striation, and becomes oval or round in transverse section. A colloid degeneration occurs, with proliferation of the nuclei of the sarcolemma. The fibre now appears of a homogeneous grey colour, and is very brittle. As it atrophies the connective tissue of the muscle increases in amount. The bone-marrow is said to be normal.

Symptomatology.—As the cause of the disease is unknown, and the invasion is insidious, the incubation period is also unknown. Hamilton Wright places it at some ten to fifteen days.

The disease is insidious in its onset, and is characterized by gastro-intestinal, cardiac, and nervous symptoms. For purposes of description three types may be recognized-- viz., (1) the acute pernicious form; (2) the typical form; (3) the rudimentary form.

1. **Acute Pernicious Form.**--The acute pernicious form may exhibit itself in several ways. The most acute is when the person, without previous illness, suddenly dies, and the autopsy reveals that he has died of beri-beri.

The more usual history is that the patient feels a disinclination for food, followed in a short time by a sensation of depression or pain in the epigastrium, and nausea. Tenderness is evinced if pressure is made over the pylorus or duodenum, while the throat is seen to be congested. The temperature is usually normal, though slight febrile rises have been recorded. Soon the heart symptoms, characteristic of the attack, appear in the form of a sensation of oppression over the heart, throbbing vessels in the neck, epigastric pulsation, cardiac palpitation, and dyspnœa, while the slightest exertion increases the pulse-rate markedly. The right side of the heart dilates, and hæmic murmurs are heard. As a result of this cardiac disturbance the urine diminishes and dropsy appears, but this varies from being trivial to fairly considerable, with effusion into the pericardium, pleura, and peritoneum.

There may early be found patches of anæsthesia or hyperæsthesia, particularly in the course of the anterior tibial and musculo-cutaneous nerves. Paralysis now appears, and may be slight, or may be so extensive as to prevent all voluntary movements, and at the same time the anæsthesia may increase considerably.

Sooner or later the cardiac symptoms become worse: the pericardial distress becomes agony, the lungs become engorged, and the unhappy individual, unable to obtain proper aeration of his blood, gasps for breath with open mouth and expanded nostrils, while the pupils dilate. His face becomes cyanosed, his extremities cold, and he becomes unconscious, and shortly dies of cardiac failure. During this dying agony the mind is clear almost to the last. The duration of such an attack is from twelve hours to a few days.

2. **The Typical Form.**---The typical form of the disease begins insidiously with malaise, lassitude, loss of appetite, dull pain in the stomach, tenderness on pressure over the pylorus and duodenum, headache, difficulty of breathing and palpitation, often some œdema along the shin, exaggerated knee-jerks, and a sensation of heaviness in the limbs, especially in the legs. Sooner or later a difficulty in walking sets in, and the knee-jerk diminishes and disappears, or the patient may suddenly find himself on wakening in the morning unable to raise himself. If he is capable of walking, the gait is peculiar, somewhat resembling that of locomotor ataxia, but generally being more of the 'high-stepping' type, the foot being raised with difficulty from the ground, brought forward with a jerk, and lowered abruptly. He walks with a support, and

often with the legs wide apart, in order to give stability to his locomotion. He cannot stand long with closed eyes, and complains that he feels as though he were walking on something soft. In addition he suffers from cramp, and his calves are very tender, and sensations of pins and needles, burning, etc., may be felt. It will be noticed that the anterior tibial and the peroneal muscles are mostly affected, and that often there is a tendency for the foot to assume the equino-varus position, and that ankle-drop is often seen.

The forearms may also be paralyzed, and wrist-drop, with great loss of power in the grip, may be noted. As the paralysis proceeds the muscles waste, and electrical excitation is much altered. Miura's rule is that if the foot can be flexed on the ankle, the excitation is only diminished; if only the toes can be dorsally flexed, there is a partial reaction of degeneration; but if no dorsal movement is capable of being made, then the reaction of degeneration will be fully developed. The paralysis spreads to the muscles of the calf, the muscles of the thigh, and the gluteal region, and to those of the hand and arm; then to the abdomen, the diaphragm, the intercostals, and the larynx, and, in rare cases, to the intra- and extra-ocular muscles.

Fletcher has drawn attention to jongkok, or squatting test The person places both hands on the top of the head, and slowly squats down on his heels, and then rises up again. In beri-beri this cannot be performed.

Associated with the paralysis there is at first hyperæsthesia especially in the calf muscles; paræsthesia, as already mentioned; and partial anæsthesia, which may be characterized by saying that the patient feels as though he were touched through some protecting cloth. There is also loss of sense of heat, and cold, and pain. This anæsthesia varies much in site and extent. Usually it begins about the feet and wrist, and moves upwards over the legs, thighs, forearms, and arms, and down into the fingers. It is this numbness of the fingers which incapacitates the patient from doing many simple actions. There is said to be a peculiar ring of anæsthesia around the mouth. The areas of loss of sensation do not correspond with segmental or nerve areas, but are remarkably patchy. The nerves of the affected regions may be tender.

The heart is also markedly affected, being dilated, especially the right side, with a diffuse apex-beat, a spacing of the sounds, so that the intervals may be nearly equal; while systolic murmurs may be heard, and reduplication of the second sound is common, particularly over the pulmonary area. Palpitation and epigastric pulsation are common, as is pulsation of the carotids and veins of the neck. The pulse is usually much increased in frequency and low in tension. The great danger of the disease is death from sudden cardiac failure.

The *blood* does not show much abnormality beyond a certain amount of anæmia. The differential leucocyte count contains about

58 per cent. of polymorphonuclears, 36 per cent. of lymphocytes, 4 per cent. of mononuclear leucocytes, and 2 per cent. of eosinophiles.

The *cerebro-spinal fluid* is generally normal. Lumbar puncture rarely shows, in our experience, any alteration of pressure, although a few authors have noted an increase.

The *urine* may be much diminished when there is œdema, but when this is passing off there is a large increase in the quantity. The total solids are said to be below normal, urea and chlorides being diminished, phosphates and indican being increased, and albuminuria being rare.

Dropsy may or may not be present, but some œdema, most marked anteriorly in the legs, is a practically constant symptom. It usually begins along the shin in the form of a rather solid œdema. It may spread over the legs into the scrotum, on to the abdominal wall, and into the face and arms, and is characterized by being at times in peculiar localized patches, and if it takes place in the muscles, gives rise to an appearance like pseudo-hypertrophic paralysis. Along with the cutaneous œdema there is often exudation into the peritoneal, pleural, and pericardial cavities.

When the dropsy is marked there may be a great diminution of the urine. This dropsical condition is often improperly considered to form a separate variety of the disease, and is called the 'wet,' 'hypertrophic,' or 'dropsical' form, while another variety, called 'dry' or 'atrophic' beri-beri, is mentioned by many authors, the two forms being merely the early and late stages of the disease.

The tongue is usually clean; the throat may be slightly congested; digestion is fair, but a large meal will increase the præcordial or epigastric distress. Vomiting is a bad sign. The bowels are often constipated, the temperature normal or subnormal. The urine may be diminished, increased, or normal in quantity, according to the presence, the passing off, or the absence of œdema.

The larynx may be paralyzed partially or completely, and the voice rendered raucous or lost. The lungs may be œdematous.

In this condition the patient may remain, at times better, at times worse, for weeks and months, and may proceed slowly to recovery, with, of course, deformities if paralysis remains, or may die suddenly of cardiac failure when sitting up or getting out of bed, or from some complication.

3. **Rudimentary Form.**—There is a rudimentary, abortive, or ambulatory form in which the symptoms are so slight that perhaps the sufferer does not seek medical advice, but in whom there may be first increase and then diminution of the knee-jerks, patches of anæsthesia, some muscular weakness, some gastric catarrh, and general malaise. Repeated attacks may occur.

Complications.—Whenever fever develops in a beri-beri patient there is sure to be a complication. The most common are tuberculosis, dysentery, and malaria.

Sequelæ.—Many authors do not believe in sequelæ to beri-beri, but certainly there may be the contraction left after the paralysis and anæmia, and attacks of palpitation may occur.

Diagnosis.—The principal positive signs on which to base the diagnosis are: (1) Loss of knee-jerks; (2) patches of anæsthesia, and occasionally hyperæsthesia, on the legs; (3) pain on pressing the calf muscles; (4) œdema along the shin; (5) absence of marked albuminuria; and (6) the absence of fever.

Suspicious early signs in endemic areas are loss of appetite and a desire for lighter food, together with tenderness over the pylorus and duodenum, with exaggerated knee-jerks.

Several diseases have to be distinguished from beri-beri: first of all the different kinds of *peripheral neuritis* e.g., alcoholic neuritis, by the history and the general tremulousness; arsenical neuritis, by the abdominal pains and the diarrhœa; lead paralysis, by the colic and the blue line of the gums.

Secondly, *dropsies* due to heart disease are recognized by the murmurs and the history of rheumatic fever, or other infectious disease; kidney disease, by an examination of the urine; ankylostomiasis, by the ova being found in the fæces; epidemic dropsy, by the fever and the absence of anæsthesia and paralysis; malarial cachexia, by the enlargement of the spleen, and perhaps the parasites in the blood; and kala-azar, by the enlarged spleen and liver.

Thirdly, certain *diseases of the spinal cord*; myelitis, by the loss of control over the bladder and rectum; locomotor ataxy, by the Argyll-Robertson pupil; pellagra, by the skin eruptions.

Fourthly, *certain intoxications*, such as ergotism by the gangrene and the history, and lathyrism by the absence of tender muscles.

Prognosis.—The acute pernicious form is always fatal, the rudimentary never. The general mortality varies in different countries, as follows:—

	Per Cent.
Sumatra	60 to 70
Hong Ko	18·6
Malaya	10·7
	2 to 6
	2·5 to 3·

But it apparently depends upon many things, of which the most important is the avoidance of sudden cardiac failure. If the patient is treated carefully in bed the danger is much diminished, but if he is allowed to sit up and move about the danger is great. Complications are most unfavourable.

An attack does not confer an immunity. On the contrary, it rather predisposes to another attack.

Observers who believe in the infectious nature of the malady are generally of opinion that there are no relapses, but that reinfections, even shortly after an attack, are common.

Treatment.—The treatment is essentially symptomatic, the patient being placed in bed, and care being taken to avoid anything which is likely to bring on cardiac failure. Especial care is required if the patient gets up or moves about. A cardiac tonic, in the form of strophanthus or digitalis, is advisable, and amyl nitrite, nitroglycerine, or trinitrin should be placed at hand, in order that they may be used at once if a sudden cardiac attack takes place. If the attack is severe, with great embarrassment of the right heart, it has been advised to perform venesection, and remove some eight ounces of blood. Oxygen is useful during the attacks of dyspnœa. For the paralysis strychnine should be administered, and the muscles massaged to prevent atrophy and cramps. Electrical excitation is also good.

If possible, the patient should at once be removed from the place in which he is supposed to have acquired the disease.

Braddon strongly recommends atropine either as the alkaloid in hypodermic injections of $\frac{1}{150}$ to $\frac{1}{50}$ grain, according to the urgency of the symptoms, or in the form of the tincture of belladonna. He considers that the atropine is specially useful in cases of dyspnœa due to cardiac failure and pulmonary embarrassment, while he gives a mixture of tincture of belladonna $\frac{1}{2}$ drachm, tincture of scilla $\frac{1}{2}$ drachm, and citrate of potash $\frac{1}{2}$ drachm, in 4 ounces of water three times a day for three or more days.

With regard to after-treatment, any deformity, such as club-foot, must be rectified, as described in works on orthopædic surgery. Fraser and Stanton have prepared a remedial agent on the lines indicated by their researches, and this should be tried when available. Only harmless rice—*i.e.*, brown rice with more than 0·4 per cent. of phosphorus pentoxide—should be given to the patients, and care should be taken that it is cooked in ordinary pots, and not under pressure. Thomson and Simpson recommend a full diet with 1 ounce of yeast and 200 grammes of katjangido-beans daily. Chamberlain and Vedder recommend that 5 c.c. of an extract of rice polishings be given daily to infants suffering from beri-beri, and this is administered in 20-drop doses every two hours. The patient must be placed upon a good nourishing diet, with plenty of proteid and good vegetables, and rice should be eliminated from this diet. Careful nursing is necessary because of the danger of cardiac failure, and good hygiene is also necessary.

Prophylaxis. Rice should be avoided as a staple article of diet, but if it has to be used it should be in the form of the Indian, country rice, or paddy, variously described as the cured, stale, unpolished, or parboiled rice. Great care should be taken with the cooking, for a good rice can be converted into a harmful rice by cooking, which should always be performed in ordinary pots, and never under pressure by steam. With regard to the different kinds of rice, Schüffner and Kuenen find that Rangoon rice contains 0·42 to 0·46 per cent. of P_2O_5, while Siam and Java rice is much lower. They maintain that there should be a rice reform, and that a minimum legal limit of 0·5 per cent. P_2O_5 for dry rice should be imposed, or, failing this, the substitution of other foods, to make up the deficient ingredient, and a strict control of cured rice—*i.e.*, white rice. Pregnant and nursing women especially should have a liberal diet and harmless rice.

A good nourishing diet is most important.

Good hygienic surroundings—*i.e.*, good ventilation, the avoidance of overcrowding, plenty of sunshine, and exercise in the open air—may be mentioned.

It is as well to thoroughly disinfect with Clayton gas or sulphur and formalin any room in which beri-beri patients have been living, or any infected house or ship.

SHIP BERI-BERI.

Synonym.—Norwegian Beri-beri. Some authorities consider ship or Norwegian beri-beri to be a separate entity from tropical beri-beri, and believe it to be a deficiency disease taking an intermediate position between true beri-beri and scurvy. Clinically, however, the condition is identical with tropical beri-beri, and runs the same course.

INFANTILE BERI-BERI.

Synonyms. *Philippines:* Taon, taol suba.

Infants nursed by mothers suffering from beri-beri, and living on a defective dietary in the Philippine Islands, suffer from œdema, dyspepsia, and cyanosis, and often die suddenly. Post-mortem investigations show degenerations in the vagi, phrenics, intercostals, and anterior tibial nerves, but not so extensive as in adults. Chamberlain, Vedder, Andrews, and others conclude that this is an infantile beri-beri due to some deficiency in the mother's milk, and find that it causes 56 per cent. of the infantile mortality in the Philippines.

EPIDEMIC DROPSY.

Synonym.—Acute anæmic dropsy.

Definition.—Epidemic dropsy is an acute infectious disease of unknown cause, characterized by fever, dropsy, an erythematous eruption, and sometimes cardiac symptoms, but without paralysis or anæsthesia.

History.—In 1876-77 there was a great famine in Southern India, during which a dropsical disease, at the time called 'beri-beri,' was noted. It is possible that this dropsical disease was conveyed in some way from Madras to Calcutta, for in 1877 there was an outbreak of epidemic dropsy for the first recorded time in that city. It appeared when the rains were over, and extended through the cold season into 1878, disappearing when the warm weather commenced in April. It recurred again, and followed the same course in the cold season of 1878 and 1879, and it disappeared in the warm weather of 1880, reappearing this time in the warm weather of 1881. It only attacked natives of India, but it spread from

Calcutta to Shillong, Dacca, and South Sylhet, and to Mauritius, by means of labourers passing through that town. Mauritius became infected in 1878, and was clear of the disease in 1879.

No further accounts of the complaint appeared until 1901, when it was again recognized in Calcutta and Madras. In 1902 it occurred in the Barisal Gaol in Bengal, and in 1907 it occurred in Assam and the two Bengals. It is probable that during the intervening years it has really been present in some part of India, but has been called 'beri-beri.' Greig has come to the conclusion that it is a deficiency disease.

Climatology.—The disease is met with in India and Mauritius, and generally in the cold season. Recently cases of this condition have been reported by Leporini from Cirenaica.

Ætiology.—The causation of the disease is unknown, but there are various theories—*e.g.*, (1) that it is beri-beri; (2) that it is a post-dysenteric anæmia or hydræmia; (3) that it is due to nitrogen starvation; (4) that it is due to eating Burma rice, the action of which is explained in various ways; (5) that it is dál poisoning; (6) that it is a special bacterial disease conveyed from person to person by the bed-bug.

This latter is Delany's theory, and is supported by the fact that the disease is epidemic, and spreads apparently by the agency of human beings, but not from man to man; that it begins with an initial fever, and has a rash, and that there is a local house infection; and, finally, by its sudden disappearance and reappearance. Other theories are that it is a ptomaine poisoning, or a bacillus in fish, or a rust or fungus on rice.

Pathology.—No remarks can be made on this part of the subject.

Morbid Anatomy.—There is subcutaneous œdema and fluid in the peritoneal and pleural cavities. The mouth and pharynx are œdematous, and the œsophagus may be ulcerated. The stomach is very congested, and may show hæmorrhagic patches, and the jejunum is congested, as are the mesenteric glands and the liver. The pancreas is normal. The aryepiglottidean folds and the lungs are œdematous and congested. The kidney is congested, and may show cloudy swelling, but the bladder is normal. The spleen is shrunken; the pericardium may be normal, but the heart is dilated.

Symptomatology.—Generally there are no distinct prodromata: occasionally the onset of the disease is preceded by diarrhœa.

Epidemic dropsy begins with an attack of fever without any initial rigor, the temperature rising to 99° to 104° F., and continuing of low type with remissions and, later, intermissions for a variable period of time, sometimes as long as a month. Associated with the fever, and, indeed, the most constant and characteristic symptom, is the dropsy, which, beginning in the feet and legs, may spread up the thighs to the abdomen, and even to the hands, arms, and face.

There is distinct anæmia after the disease has lasted a little time. Rogers records a count of 3,090,000 erythrocytes per cubic centimetre, and a hæmoglobin count of 54 to 65 per cent. The colour index is said by other observers to be about normal, and the proportion of white to red cells to vary from 1 to 430 at the invasion, to 1 to 384 in the course, to 1 to 615 at the end. Leucocytes are apparently always increased in number, but only slightly. The differential count is:—

	Per Cent
Polymorphonuclears	60·2
Lymphocytes	21·4
Mononuclears	11·7
Eosinophiles	6·7

No animal or vegetal parasites have been discovered in blood which is sterile.

The condition of the urine is described as very variable, but there is no albumen and no casts are to be found.

Effusions into the peritoneal and pleural cavities may take place. The alimentary canal is early irritated, and vomiting and diarrhœa are common occurrences. A rash appears early on the extremities in the dropsical areas; it is usually erythematous or 'measly,' but vesicles and hæmorrhages may be seen. Anæmia, as remarked, is progressive during the disease, and there may be cardiac dilatation with hæmic murmurs. In severe cases there may be cough and dyspnœa, due to œdema into the lungs. Recovery is the rule, but death may occur from cardiac or pulmonary complications.

Sequelæ.—The only sequela so far observed is cardiac weakness.

Diagnosis.—Epidemic dropsy shows the following characteristic signs: dropsy, slight fever, diarrhœa, rash, anæmia, and no albuminuria.

Its diagnosis from *beri-beri* is based upon the presence of fever, the persistence in some cases of the knee-jerk, the lack of paralysis, of painful muscles, and of anaesthesia. Some authorities maintain, however, that in epidemic dropsy there is no fever and no rash, and is indistinguishable from beri-beri.

Prognosis. The prognosis is favourable except in the aged, the case mortality being only 2 to 8 per cent.

Treatment. Rest in bed and the administration of calcium chloride, or iron and strophanthus, are the only remedies usually required. High temperatures should be treated by diaphoretics, quinine, and sponging.

Prophylaxis. Segregation and disinfection are recommended, but no rational prophylaxis can be advised so long as the cause remains unknown.

POTTER'S DISEASE.

In 1913 Potter in Jamaica described a disease which began with numbness, tingling cramps, loss of power, loss of hearing, and defective vision, without skin or mental symptoms, œdema or cardiac symptoms. Both sexes are attacked, generally after puberty and in rural districts. Whole families may be attacked.

WAR ZONE ŒDEMA.

In soldiers, prisoners of war, and refugees, having a very scanty and unsuitable diet an œdematous condition of the legs and feet is far from rare. It is a deficiency condition more closely related to scurvy than true beri-beri. It should be differentiated by blood examinations from a clinically similar condition due to malaria.

TROPICAL ŒDEMA.

Some years ago we called attention in Ceylon to an œdematous condition of the legs, seen especialy in new-comers and tourists in the hot season The whole leg from below the knee is affected, but if the person wears boots tightly laced, the foot and ankle do not show any œdema. There is no anæsthesia, the knee-jerks are normal, and the general condition is good. The condition is not related in any way to beri-beri or scurvy and is not influenced by a change of diet. It disappears rapidly on going to the hills. The same condition has been recently recorded by Marshall from the Red Sea and Bagdad

CHAPTER LXXII

TROPICAL POISONINGS

General Remarks—Ackee poisoning—Onyalai—References.

GENERAL REMARKS.

We have already defined a poison and discussed criminal poisoning, accidental poisoning, stimulant and sedative poisoning, and the poisons used in trial by ordeal in Chapter X. (p 161), in which we gave a brief outline of the symptoms produced by a number of these poisons, as well as some few remarks with regard to treatment.

There, however, remains one form of accidental poisoning, to which we have already referred on p. 173, to which special reference may be made here, and that is *ackee poisoning*, which was long known as the *vomiting sickness of Jamaica*, and was included in the clinical part of the last edition.

This particular variety of poisoning might also be looked upon as a form of vegetal food poisoning, a subject which is considered in Chapter XIII., p. 193.

Other forms of poisoning, such as arrow poisons, animal poisons, trade poisons, can be found in Chapters XI. (p. 180), and XII. (p. 187).

ACKEE POISONING.

Synonym.—The vomiting sickness of Jamaica.

Definition.—An acute and often fatal illness, occurring mostly in children and to a less extent in adults in Jamaica, characterized by sudden onset, persistent vomiting, causing in fatal cases collapse, and brought about by eating the unsound fruit of the ackee tree, *Blighia sapida* Koenig, or drinking the water in which such fruit has been cooked.

History.—For many years the term 'vomiting sickness' was applied to any disease associated with this symptom, but as various diseases became differentiated and better diagnoses were made, it became evident to Turton in 1904 and to Kerr in 1905 that there was a definite disease in Jamaica to which the term could be applied.

This disease only appeared in the cooler months, and was associated with vomiting and convulsions, and a death-rate of 80 per cent. to 90 per cent., the end coming in a few hours.

In 1906 Branch considered it to be a syndrome, and mentioned the ackee, without, however, being definite as to its causal effect.

In 1912 Potter, after considering cerebro-spinal meningitis, ptomaine poisoning, ackee poisoning, and cassava poisoning, came to the conclusion that it was a phase of yellow fever.

In 1913 Scott suggested that it might be fulminating cerebr[illegible] spinal meningitis, and in the same year Seidelin opposed the yell[illegible] fever and the meningitis views and believed it to be a l[illegible] disease.

In 1915 Scott, as a result of an investigation into an outbreak at Montego Bay, found that in the majority of cases *ackees* formed part of the last meal taken in health, and that they could not be excluded in a single case. Persons taking soup or pot-water made with ackees developed symptoms in two hours, and death nearly always resulted.

The ackee is the fruit or aril of *Blighia sapida* Koenig, belonging to the natural order Sapindaceæ, and, being a native of West Africa, is merely an introduced plant in Jamaica.

Only unsound ackees cause the symptoms, and an ackee is unsound (1) when it is unopened; (2) when it is picked from a decayed, bruised, or broken branch; (3) when it has been forced open; (4) when it has a soft spot.

In 1917 Scott confirmed this view as to the causal effect of the ackee, and by his experiments upon animals demonstrated the nature of vomiting sickness.

Climatology.—So far the disease is only known in Jamaica, but it must be remembered that the tree is a native of West Africa. We, however, do not know whether the fruit is used as a food in this country, and, at all events, up to the present no one has reported the poisoning from that part of the world.

Ætiology.—Vomiting sickness is caused by eating the *unsound* fruit of *Blighia sapida* Koenig, the ackee plant, or taking the soup or 'pot-water' made with this fruit. These latter are the more severe cases, because the poison appears to be extracted by boiling with water. Alcoholic extract of unsound ackees is not poisonous. The watery extract, on the other hand, when administered to cats and dogs, produced the same symptoms and mortality rate as in man, and after death the same post-mortem signs were found. Herbivorous animals are unaffected. The poisoning takes place in the months from November to April, which corresponds with the *ackee season.* Several members of a family are taken ill at one and the same time, as would be expected from a food poisoning. It also occurs among near neighbours in the settlement, and is rare in white children and East Indians, being confined to the children of the indigenous population. There is no indication that sex plays any part in the ætiology, which must be looked upon as an acute poisoning. A case of known ackee poisoning occurring in man showed the same symptoms, cause, and post-mortem changes as cases of vomiting sickness, and as the experimental animals.

Morbid Anatomy.—There is a general hyperæmia, with a tendency to hæmorrhages in various organs. The mucous membrane of the stomach and the bowels is congested, while the lumen of these organs may contain a dark slimy substance. There is fatty degeneration in the liver and kidneys, and in the former case this change is said to be more acute than in phosphorus poisoning. Microscopically necrobiotic changes are found in the cells of the liver, kidneys, and pancreas.

Pathology.—The illness comes on suddenly in a person who has previously been in perfect health, and is characterized by primary or gastric vomiting, followed by a few hours of temporary cerebral vomiting, which is rapidly followed by convulsions, coma, and death, the average duration of the illness being twelve and a half hours.

The poison appears to be an irritant to the stomach, and to cause vomiting, which may rid the body of it, when the patient rapidly recovers; but if it remains in the system it acts upon the nervous system, causing the cerebral vomiting, convulsions, and coma, which, apparently, always end in death.

Symptomatology.—Somewhere about midnight a child wakes up and complains of pain in its stomach, in a little time vomits its last meal, and after this feels better. In certain cases no further symptoms occur, and there is a rapid recovery.

More usually, however, after a period of temporary relief the vomiting commences again, and may be accompanied by fever, while the vomit consists of frothy mucus. These symptoms continue until the child passes into a state of collapse, with cold sweats, a weak and rapid pulse, and irregular respirations.

These symptoms invariably lead to death, which is preceded by convulsions.

Variety.—In rare cases there is no vomiting, and only the cerebral symptoms, drowsiness, convulsions, and coma, leading to death. This is the so-called 'vomiting sickness without vomiting.'

Diagnosis.—The cardinal points in the diagnosis are:—Its endemicity; its seasonal prevalence; its sudden onset in members of one family or in neighbours; in native children without regard to sex; the quick complete recovery of some cases, while others, after showing cerebral symptoms, end fatally; and finally the evidence of having partaken of a meal containing ackees or their extracts. It can be diagnosed from *yellow fever* by the absence of the black vomit, and from *cerebro-spinal meningitis* by an absence of Koenig's sign and of the meningococcus.

Prognosis.—This is very bad, as some 80 to 90 per cent. of the patients die. If recovery is to take place, it is rapid and complete.

Treatment.—No specific treatment is known.

Prophylaxis.—Instruct the people not to use unsound ackees. This has been done, with the result that in 1916 there were only three deaths from vomiting sickness in Jamaica.

ONYALAI.

Synonyms.—Edyuo (Bukoba); Kafindo (Congo).

Definition.—An acute disease of unknown causation, characterized by the appearance of bullæ containing blood on the surface of the body, the tongue, soft palate, or buccal mucous membrane.

History.—The disease was discovered by Yale Massey in Angola in 1904, and fully described by Wellman later in the same year in Portuguese West Africa, and by Feldman, in 1905, in East Africa, where it is called 'edyuo' by the natives of Bukoba. Mense (1906) thinks that the 'kafindo' disease of the Unyamwezi people of the Congo is the same disease. Hæmorrhagic bullæ in the mouth, but without general symptoms, have been described by Maxwell in Changpo, South China, as being due to the accidental introduction into the mouth of a kind of spider's web.

Ætiology.—This is unknown, but Mense thinks it may be some kind of poisoning, perhaps with some species of the Euphorbiaceæ. Wellman considers that it is not a manifestation of malaria; nor is it a vegetal poisoning, nor a snake-poisoning, though the bite of *Bitis arietans*, the puff-adder, simulates some cases closely. Neither trypanosomes nor bacteria were found. It is not a purpura hæmorrhagica, nor Henoch's purpura, nor Schönlein's disease.

Symptoms.—The onset is sudden, and is accompanied by lassitude and a dazed appearance. Sometimes the parotids are tender, and the eyes may be somewhat reddened, and in about 66 per cent. of cases there is a slight rise of temperature. Numbness and pain in various parts of the body may be noted.

The appetite is poor: bullæ may be seen on the tongue and in the mouth and pharynx, while they also occur in the œsophagus, stomach, and bowels. The tongue is swollen and painful. Vomiting of blood is not rare, and bloody diarrhœa may take place. Hæmaturia has been noted, and cerebral hæmorrhage, with the usual signs, has been seen. It is believed that hæmorrhage into the pancreas, liver, and spleen, may take place in some cases. Bullæ may also appear in the skin, ranging from the size of a split pea to several inches in diameter. The typical bullæ, whether on a mucosa or in the skin, extend deeply, involving the submucosa or the corium, and are crossed by fibrous trabeculæ, in the meshes of which lies partially coagulated blood, which appears dark through the skin or mucosa. The red corpuscles are not disintegrated, and can be seen by the microscope.

The disease is said to have a tendency to recur two or three times.

Diagnosis.—The diagnosis from snake-bite may be effected only by the history, as the bullæ may not be visible on the skin or mucosa. Malaria can be excluded by the blood examination. Schönlein's disease, or peliosis, is diagnosed by the rash, painful swelling of the joints, and the purpuric eruption. Henoch's purpura is met with generally in children, and has joint symptoms as well as a rash.

Prognosis.—Wellman reports three deaths in fourteen cases, and says that the malignancy varies in different seasons and districts.

Treatment.—Wellman thinks that arsenic in full doses is the best treatment. He says the natives use empirically ***Geigera wellmani*** Hutch and ***Albizzia anthelmintica*** A. Broga. Massey recommends large doses of bicarbonate of soda and cod-liver oil.

CHAPTER LXXIII

PELLAGRA

Synonyms — Etymology — Definition — History — Climatology — Ætiology — Pathology — Morbid anatomy — Histopathology — Symptomatology — Diagnosis — Prognosis — Treatment — Prophylaxis — References.

Synonyms.—*Italian*: Umor Salso, Scottatura di Sole, Malattia della Miseria, Mal del Sole, Malattia della Insolazione di Primavera, Risipola Lombarda, Mal della Spienza, Mal del Padrone, Jettatura di Sole, Cattivo Male, Mal della Vipera, Calore del Fegato, Salso, Pelandria, Pellarella, Pellarina, Psychoneurosis Maïdica, Mal Rosso, Maïdismus, Lepra Italica Maïdica, Scorbuto Montano, Scorbuto Alpino, Elephantiasis Italica. *Spanish*: Mal de la Rosa, Mal d'Asturias, Mal del Hígado, Calor del Higado, Escamadura del Hígado, Flema Salada. *French*: Maladie de la Teste, La Gale de Sainte Ignace, Mal de Saint Amans, Mal des Saintes Mains, Mal de Sainte Rose, Mauvais Dartre. *German*: Der Lombardische Aussatz. *Roumanian*: Buba Tranjilor, Rana Tranjilor, Parleala, Jupuiala. *Greek*: Graeci Elephantiasis. *Egyptian*: Inshup, Qushuf, Golar, Lahooh. *South America*: Chichismo.

Etymology.—The name 'pellagra' is an Italian word, possibly coined by the peasants from two words—*pelle*, meaning 'skin,' and *agra*, meaning 'rough'—though other possible origins are also given. It was introduced into medical literature by Frapolli in 1771 in his work, 'Animadversiones in Morbum Vulgo Pelagram,' when he spelt it with only one *l* instead of with two.

Definition.—Pellagra is an endemic disease, usually of long duration and of unknown causation, which is characterized by cutaneous, gastro-intestinal, and nervous symptoms, which undergo exacerbations at recurrent intervals, usually in the spring or autumn.

History.—When it is considered that pellagra has been overlooked in quite recent years in America, Scotland, and England, and probably in many other parts of the world, it will not be thought to be astonishing that ancient literature is silent as to its existence in Europe, but the absence of these references by no means proves that the disease itself was not present. Strambio finds that some of the symptoms mentioned in Hippocrates may be those of pellagra, and says that his description of 'Sollicitudo' indicates a disease resembling the mental condition found in pellagra during an acute exacerbation. We have searched through Hippocrates, and have been unable to find anything which to our mind bears any resemblance to pellagra. The peculiar symptoms from which St. Francis of Assisi, who lived in a district which to this day is pellagrous, suffered, markedly resemble pellagra, as he had an eruption upon his hands and feet, associated with an extraordinary mental condition; but though these speculations are interesting, they are far too uncertain to be of any use in determining the interesting point as to whether pellagra existed in Europe before the introduction of maize by Columbus. In 1578 the disease seems to have been known in Milan as 'pellarella,' but was confounded with eczema, leprosy, erysipelas, and scurvy, and no real importance can be attached to a simple name unaccompanied by any description of the disease to which it was applied. A slightly more definite reference is found in 1713 in Ramazzini's work, 'De Morbis Artificium Diatriba,' under the heading 'Agricolæ,' where he says: 'Easdem ob causas, iis persæpe contingunt dolores colici et affecto Hippocondriaca quam ipsi appellant, il mal del Padrone.'

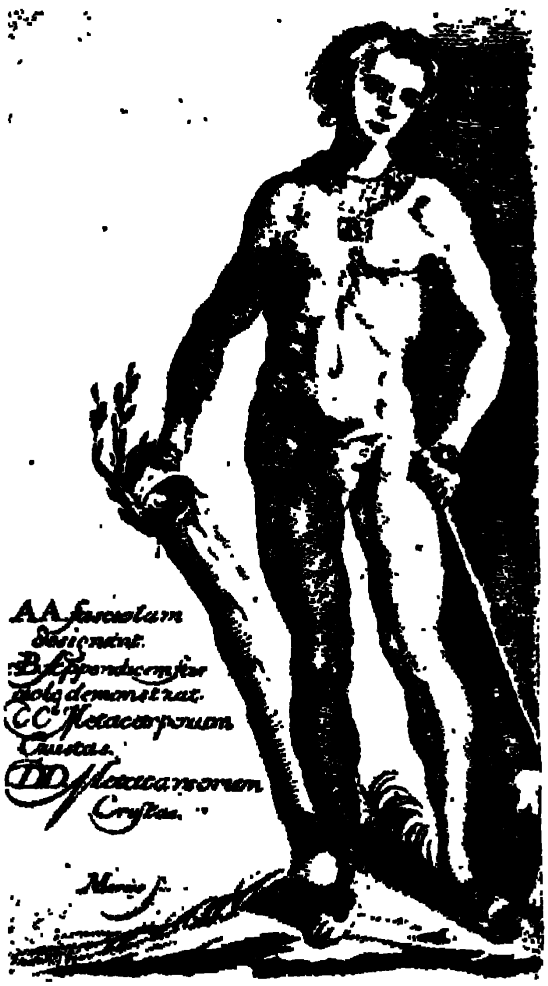

FIG. 736.—MAL DE LA ROSA. (After Casal.)

The recognition that the cutaneous, gastro-intestinal, and mental symptoms exhibited by the sufferers constituted a clinical entity was first made by Gaspar Casal on March 26, 1735, but, unfortunately, was not published until 1762, when his work, 'Historia Natural y Médica del Principado de Asturias Sequida de la Descripcion de la Enfermedad conocida por el Vulgo con il Nombre de Mal de la Rosa,' appeared. Casal gave a representation of the disease (Fig. 736), showing the eruption around the neck and down the front of the chest (called Casal's necklace), and on the dorsa of the hands and feet. With Sambon one of us has visited the Oviedo district of the Asturias in North Spain, where Casal first recognized pellagra, and find that, as regards the cases along the River Nero the disease exists as it did in his days. On December 2, 1740, a learned monk named Feijóo wrote to Casal stating that 'Mal de la Rosa' existed in his native country, Galicia. Before Casal's publication appeared the celebrated Thiéry visited Madrid, where he met Casal, and was shown cases of pellagra, and afterwards he observed one case himself. On his return to Paris he wrote a paper entitled, 'Description d'une Maladie appellée Mal de la Rose aux Asturies,' which was published in the second volume of Vandermonde's journal called 'Recueil Périodique d'Observations de Médecine, de Chirurgie, et de Pharmacie,' in May, 1755. It is pleasing to record that not merely did Thiéry give a most excellent description of the clinical signs of pellagra, but he also gave full credit to Casal for his, as yet unpublished, great discovery.

These publications of Casal and Thiéry laid the foundations of the modern knowledge of pellagra. We will now turn to the various countries, and study, very briefly, the history of the disease therein.

Italy.—Early in the eighteenth century the disease appears to be well known to the medical men of Cremona and Cremasco, as well as to Antonio Terzaghi at Sesto Calende on Lago Maggiore, and to Francesco Zanetti, who recognized it in 1769 at Canobis, also on Lago Maggiore. It will thus be seen that pellagra, hinted at in 1578 in Milan, written about by Ramazzini in 1713, had become a disease well known to the general practitioner and peasantry, and only required an historian to become recognized by the medical profession. This historian was found in Francesco Frapolli, one of the physicians in the large hospital in Milan, who in 1771 published his work, 'Animadversiones in Morbum Vulgo Pelagram,' in which for the first time the word 'pellagra' (spelt with a single *l*) was used. This work, followed by those of a number of authors, drew more attention to the disease, with the result that the Patriotic Society of Milan offered a prize for the best essay on the subject, while the Kaiser Joseph founded a special hospital for pellagrins, and placed it under the charge of Gaetano Strambio, whose justly celebrated work, 'De Pellagra,' appeared in three volumes during the years 1786-1789. In 1787 two young Dutch doctors, Jensen and Hollenhagen, and a young Frenchman, Levacher de la Feutrie, visited Italy to study pellagra, concerning which they published reports on their return to Holland and France. In 1799 Chevalier gave an account of Jensen's work in the *London Medical Review and Magazine*. In this way the knowledge of the disease called pellagra started and spread.

In the meanwhile a disease called 'Scorbuto Alpino' had been definitely recognized by Giuseppe Antonio Pujati in 1740 in Feltre, to the north of Venice, and the same disease was found later by Antonio Gaetano Pujati, the son of Giuseppe Antonio Pujati, and Nascimbeni in the Venetian Friuli, and this disease found its historian in Odoardi, a pupil of the older Pujati, who in 1776 published his work, 'Di Una Specie Particolare di Scorbuto,' in which an account of Professor Pujati's discoveries was given. In this way the knowledge of the disease 'Scorbuto Alpino' was started, so that in Italy at this time there were described two separate diseases under different names, and found in different regions; and it was not till Fanzago in 1789 published his work, 'Memoria sopra la Pellagra del Territorio Padovano,' that these two diseases were recognized to be one and the same. After this date the literature concerning pellagra increased considerably, but no work of great importance appeared until 1810, when Marzari published his book, 'Saggio Medico-Politico sulla Pellagra e Scorbuto,' in which he laid stress upon 'maize' as the principal ætiological factor in the disease—a view which had previously been mentioned, but not so forcibly, by Casal and others. The importance of this work is that, ever since its publication, the maize theory in some form has been generally adopted in Italy. Marzari was of the opinion that it was the deficiency of the gluten in the maize which was the main agent of the disease, but he also suspected toxicity. From Marzari's time there are very numerous publications, among which may be mentioned those by Henry Holland in 1817 on the pellagra of Lombardy, published in the Medico-Chirurgical Transactions, and by Zecchinelli in 1818.

Balardini in 1845, in his work entitled 'Della Pellagra, del Grano turco quale Causa Precipua di quella Malattia e dei Mezzi per Arrestarla,' promulgated the view that the causation was a fungus growing in the maize, which fungoid growth was called 'Verderame,' and was thought to be due to *Sporisorium maidis*. This publication was of the greatest importance, as it afforded an explanation as to why the disease should attack some people and not others, and thus gave the maize theory greater importance. This subject was further studied by Costallat and others, who produced symptoms in chickens by feeding them on maize containing verderame, which were said to resemble those of pellagra.

In 1872 Lombroso began to study pellagra, and continued to do so till he died in 1909. He believed that the disease was an intoxication produced by the toxins manufactured by organisms, harmless in themselves, and growing on maize. More recently a view has been promulgated that the disease is due to good maize, which in certain people produces the symptoms of the disease, and in others does not. Such, briefly, was the condition when Sambon in 1905 began his work, which he has continued up to the present time. This work, which is mainly epidemiological, has thoroughly shaken, if not completely destroyed, the maize theory, and has brought forward many facts which support strongly a parasitic theory of the causation of the disease as well as a probability of the infection being spread by one of the biting flies.

Spain.—The discovery of the disease by Casal in 1735 in the Oviedo district of the Asturias has already been mentioned, as well as the fact that Feijóo had recognized it in Galicia. The next publication is by an Englishman, called Townsend, entitled 'A Journey through Spain,' and published in three volumes in London in 1791. In the second volume, on p. 10, there is a short clear account of 'Mal de Rosa.' This is the earliest known account of pellagra in English. In 1820 Eximeno made an inquiry into the disease, and came to the conclusion that 'Mal del Hígado,' 'Mal de la Rosa,' and pellagra were one and the same disease. In 1835 Mendez Alvaro recognized pellagra in the malady called 'Flema Salada,' and in 1847 Henriquez showed that 'Mal de Monte' was the same disease. In 1849 Roussel visited Spain, and recognized that the disease in France and that in Spain were the same clinical entity. Since that date many excellent works have been published in Spain on pellagra, notably by Calmarza and Roël, while of late the disease has been carefully studied by Huiteras, Pittaluga, and the physicians of Oviedo.

The maize theory of the ætiology of pellagra has never gained credence in Spain, and hence the term 'Spanish pellagra,' or a pellagra not due to maize, has been used by some Zeists as a medical synonym for a hoax.

Portugal. —Pellagra is known to exist in Portugal, but we are in the same condition as older writers, in that we can give no history of its recognition or spread.

France.—We have already noted Thiéry's publication in 1755, and the fact that in 1787 a young Frenchman, Levacher de la Feutrie, proceeded to Italy to study the disease, concerning which he subsequently published accounts in 1802 and 1806: but it was Hameau in 1818 who first recognized the disease in France as occurring around Teste-de-Buch, in the Plain of Arcachon. Hameau was not acquainted with the literature which had sprung up concerning pellagra, and his observations were in reality a rediscovery of the disease. In 1829 he read an excellent dissertation on the subject before the Society of Medicine of Bordeaux, under the title 'Description d'une Maladie Nouvelle.' It would appear that he considered it to be an infection in some way acquired from sheep. In all he observed no less than seventy-six cases.

There is, however, evidence in favour of the suggestion that pellagra had long existed in France, and this is to be found in the fact that the peasants used to call the disease 'Mal de Saint Amans,' because there was a statue to St. Amans in Bascons which was always moist, and this moisture was used by the pellagrins as an application to their eruption. According to Roussel, there was another curious custom followed by the peasants of the Landes, which was to visit a certain statue in which the Christus was represented with red hands. The priest was wont to apply an ointment to these hands, from which the sufferers removed a little of the ointment and applied it to their own inflamed hands, feet, face, etc. From this interesting ceremony the disease was called the 'Mal des Saintes-Mains.' Other popular names, such as 'Mal d'Arouse' and 'Mal de Sainte-Rosa,' tend to show that the common people were well acquainted with the disorder. Sambon has also informed us that some of Napoleon's soldiers became affected by pellagra during the campaigns in Italy, and certainly cases are recorded in the Hôtel Dieu and in the Hôpital Saint-Louis, while Jourdan published a paper on the disease in 1819.

Brière de Boismont in 1830 drew attention to the fact that pellagra occurred around Paris, and in 1847 Ardusset showed that the 'Maladie de la Teste' of Hameau was pellagra. In 1843 Marchand, after investigations extending from 1836 to 1842, emphasized the fact that pellagra was essentially a disease of *the country*, and not of the town. In 1845 appeared Roussel's account of his researches in France and Spain, to which reference has already been made. In 1865 Billod published his account of asylum pellagra as a pseudo-pellagra - that is to say, a pellagra not due to maize. Sambon and one of us have investigated the pellagra of the Landes, where the disease has greatly diminished, and this appears to be associated with a diminution in the malaria of the same region, which appears to be due in part, at least, to the improved cultivation of the soil, the drainage of swamps, etc., and the stocking of the waters with fish.

Austria. The disease was first noticed in the Tyrol, where it is still very prevalent, and where it is being ably studied by Merk, Weiss, and others. In 1794 Nicolas and Jambon reported its presence near Vienna.

Hungary and Roumania. In 1840 Lachaise drew attention to an epidemic of pellagra in Roumania, in 1856 Julius Theodori reported its presence in the Danube provinces, while in 1862 Bouchard pointed out that Sigmund said that the Hungarian pellagra existed solely in the vast plains bordering the Rivers Danube and Theiss —*i.e.*, in the Alföld - which were often covered by inundations. It is interesting to note that these rivers have been regulated, and that the disease is said to have considerably abated there. Be that as it may, there is to our personal knowledge a considerable amount of pellagra in Transylvania, where it has been studied by Hollander, Kaiser, and others, and in Roumania, where Babès says there are more than 200,000 cases.

Macedonia. Cases of pellagra have been observed by us in Macedonia.

The British Islands. Though reported as long ago as 1860 by Brown, and again in 1909 by Cranston Low in Scotland, no attention has been seriously paid to the disease until recently, when Sambon and one of us, searching through the British Islands, came across cases in both Scotland and England, and it appears probable that more definite information with regard to the spread of pellagra in these islands will soon be forthcoming. The interest with regard to these cases is that while it is impossible to mathematically exclude all possibility that a patient had never tasted a grain of maize, still it would be straining the maize hypothesis to an unjustifiable extent to try to make it apply to all of these cases. It is interesting to note that pellagra has been found as far north as the Shetland Islands. Of late years quite a number of cases of pellagra have been reported in the British Isles.

Iceland.—We have no information as to the presence of pellagra in Iceland, with the sole exception of a statement by Holland that he had seen cases in Iceland resembling the pellagra which he had observed in Italy.

Africa.—Though first noticed in Egypt by Pruner in 1847 under the term 'leproses,' its recognition therein is principally due to Sandwith, who found it in 1893, and to Keatinge and Warnock, who have not merely kept that knowledge alive, but have added considerably to the study of the disease. There is, however, still a tendency to consider pellagra a part of the syndrome of ankylostomiasis. More recently pellagra has been recognized in other parts of Africa, and it is possible that it will eventually be found to be widespread in that continent.

America.—Notwithstanding careful inquiries, Wood has failed to discover any evidence of the existence of pellagra among the North American Indians during the eighteenth century, but he has found some evidence of cases in the early years of the nineteenth century. In 1864 Gray and Tyler first definitely reported cases in them, but though at times recognized, the disease was not generally admitted to be present until 1907, when Searcy reported eighty-eight cases, of which fifty-seven were fatal. From that date the works of Babcock, Lavinder, Siler, Roberts, Niles, Wood, and many others, have made the disease well known. In the meanwhile, pellagra has been recognized in the West Indies, Mexico, and other parts of America.

Asia and Oceania.—During recent years pellagra has been recognized in India, the Straits Settlements, the Philippine Islands, and the Sandwich Islands.

Summary.—The above history of pellagra demonstrates the ease with which the disease may be overlooked, even when abundantly present, by well-trained and most competent observers. It also impresses us with the fact that pellagra should be looked for in every country, without any preconceived idea as to its ætiology.

Climatology.—It appears probable that before many years have passed, pellagra will be found to be prevalent all over the world. At present it is known to exist in:—

Europe.—Scotland, England, France, Spain, Portugal, Italy. Austria (including the Tyrol, Bosnia, and Herzegovina), Hungary, Roumania, Russia, Serbia, Macedonia, Bulgaria, Greece, and Turkey. Cases have been reported as far north as the Shetland Islands.

Africa.—Algeria, Tunisia, Egypt, Central Africa, Rhodesia, and South Africa.

Asia.—Asia Minor, Persia, India, and the Straits Settlements.

Oceania.—Sandwich Islands.

America.—United States, Mexico, West Indies, Brazil, Columbia, and the Argentine.

The feature of the last few years with regard to the climatology has been the recognition of pellagra as an endemic disease in Scotland, England, and the United States. Mere geographical distribution *per se* is not so important as an epidemiological inquiry into the actual localities in which the disease occurs. Pellagra is essentially a disease of long duration, and patients are capable of moving far from the place in which the first symptoms appeared, and, again, the first symptoms often appear in early childhood and reappear after some years' interval, when the patient may be living in quite a different district from that in which he resided during his younger years. It is therefore necessary to prepare and study spot maps showing where the patients were first attacked by the signs and symptoms of the disease, and this is being done at the present time by Sambon, whose results will be awaited with interest. In general it may be stated that inquiries of this nature show that by far the larger number of cases occur in country districts, and not in towns, and that the densest localization is in houses near or alongside certain streams. In fact, study the localization in what country you will, as we have done in France, Spain, Italy, Austria, Hungary, Roumania, and Egypt, it is impossible not to be impressed with the relationship between pellagra and water. Generally the water is moving, and often it is moving rapidly, but this last does not appear to be absolutely necessary. As a rule, the nearer the dwellings are to such water, the greater the number of cases. Cases do, however, occur at a distance from water, but inquiry will often demonstrate that the affected people work near or have been in some way connected with a stream. Cases do occur in towns, but they are relatively few, and careful inquiry will usually elicit a perhaps almost forgotten fact that the disease really began after some visit to the country. Inquiries, however, must be made with care, otherwise wrong impressions may be obtained. One of the most interesting cases

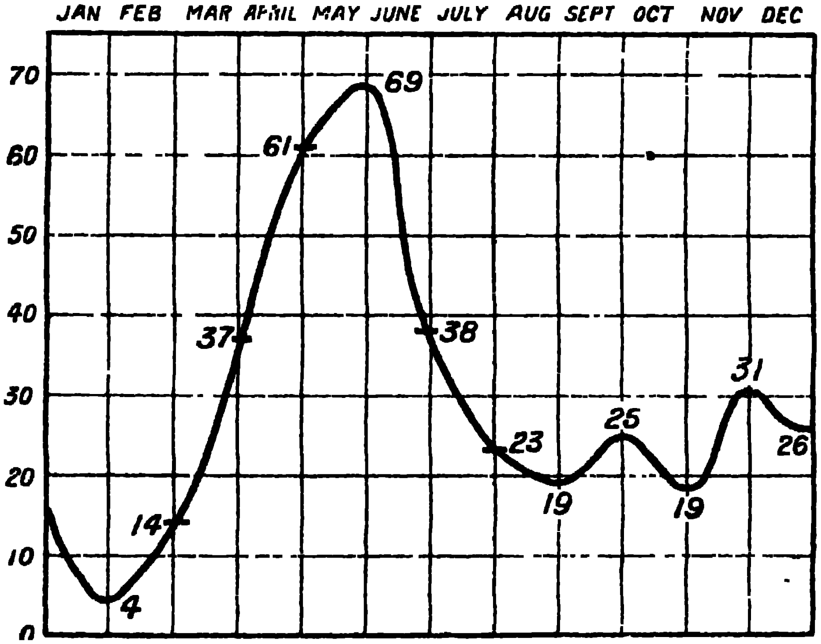

FIG. 737.—SEASONAL VARIATION IN THE ADMISSIONS FOR SIX YEARS OF PELLAGRA CASES INTO THE KASR-EL-AINY HOSPITAL, CAIRO.

(Specially prepared by Keatinge and Stiven.)

which we have met with was that of a young boy who was supposed never to have left a large town, and yet was suffering from pellagra. Careful inquiry elicited the fact that he was in the habit of going for a day or so every year to stay with some relatives who lived in a pellagrous area, and the time of the year chosen for this visit was one in which acute cases occurred. In a locality pellagra usually occurs among the poor, especially among field labourers; but it may also occur among the rich and among persons who habitually work indoors; it is, however, usually not difficult to trace a relationship between the commencement of the disease and a visit or residence in some pellagrous area, and very often, again, a relationship to water.

With regard to seasons, there is a universal consensus of opinion that most attacks appear in the spring or early summer (in Egypt with the Khamseen), after which there is a diminution in the cases, and although attacks may begin in the summer, they are not common. In the autumn, however, there is a definite, though secondary increase in the number of cases, which decrease almost to nil in the winter. These statements are well borne out by the curve of pellagra admissions into the Kasr-el Ainy Hospital, Cairo, for the years 1900-1911 inclusive. This curve, for which we are indebted to the kindness of Dr. Keatinge, was most carefully prepared by Dr. Stiven, and demonstrates the incidence of pellagra as seen in that hospital.

Pellagra may occur in hilly or even mountainous regions, where it is often very common as, for example, the Tyrol--but can equally occur on the flat alluvial deposit of rivers-- as, for example, the delta of the Nile. It would appear that pellagra extends from near the Equator to the Shetland Islands in the north, and to South Africa in the south, and that it encircles the world in an easterly or westerly direction. In our experience the one important factor to be certain that pellagra is endemic in a region is to find it in very young children born in the region from which they have never stirred.

To summarize, pellagra has a world-wide distribution. It occurs in hills and plains. The cases are densest near moving fresh water, and usually begin in spring or autumn.

Ætiology.- The causation of pellagra is at the present time *unknown*, so that we are compelled to consider possibilities instead of facts- a point which we desire the reader to bear in mind while perusing the remarks we are about to offer for his consideration.

The extraordinary theories which we have found still in existence among medical men in the various pellagrous regions which we have visited are:--

1. That it is not a disease, but merely dirt, and can be cured by turpentine, soap, and water. This theory of course applies only to the quiescent stage of a very chronic case, and is easily excluded by a little knowledge of the disease.

2. That it is not a disease *per se*, but merely a series of stray symptoms, and that no one has studied the cases from the commencement of the disease

to its fatal termination. A study of merely Hameau's writings, excluding all the modern Italian, Roumanian, and American literature on the subject, would, we think, satisfy any unbiassed person that this view is untenable.

3. That it is not a disease *per se*, but merely symptoms of some other well-known disorder. The disease which it is most commonly said to belong to is ankylostomiasis, but most of our readers will themselves have treated many cases of ankylostomiasis without meeting with the symptoms of pellagra, and many will be acquainted with pellagrins who show no signs of ankylostomiasis.

The above can be easily dismissed, and would not have been mentioned if we had not personally met with believers in all of them. With regard to the more likely theories, we must discuss the following:—

I. The deficiency theory.
II. The maize theory.
III. The parasite theory.

I. The Deficiency Theory. —In Chapter IV., p. 94, we have briefly traced the evolution of foods and the effects of a low protein dietary, as well as the effects of certain nitrogenous complexes on man, and therefore need not recapitulate what we have written on those pages. Arguing upon the theory of the causation of beri-beri by the absence of a nitrogenous complex, some people have asked whether pellagra may not be due to the lack of some nitrogenous complex in the food; and, further, it has been suggested, or rather hinted, that this might explain, not merely the maize theory of pellagra, but those cases in which no maize has been eaten, but in which the diet has been largely oatmeal or rice. Thus, Nightingale in his paper on Zeism, which appears to us to be pellagra, finds that when steam-milled mealie bread alone was supplied to the prisoners in the Victoria Gaol in Rhodesia the disease broke out, and when this was stopped, and meat, vegetables, and rice were substituted, the epidemic ceased; and when hand-milled rapoko (maize) was obtained, the effect, in Nightingale's words, was 'immediate and almost magical,' as the patients began quickly to recover. In this rapoko the husk was not eliminated by the hand-milling. The parallel between this and beri-beri is obvious. In our opinion there is one great flaw in this theory, and this is that pellagra may occur in people provided with an excellent dietary. To this it might be replied that some peculiarity of the individual's body destroyed the necessary vitamine, but this argument is, to our minds, rather strained. Modern work tends at the moment to support this theory as being the true course of the disease, but there are many difficulties, and it cannot be said to be proven.

II. The Maize Theory. —Much of a most convincing nature, if left unanalyzed, can be written in support of the maize theory in general. It can be pointed out that maize (*Zea mais* Linnæus) was originally a native of America, where it has been found in its ancient form of small grains in the graves of the Incas, and that it was introduced by Columbus or his followers into Europe, where it did not grow well in certain countries, like the British Islands, which, therefore, remained free from the disease until the nineteenth century, when importation of maize took place in greater quantities than heretofore, but where now there is plenty of maize sold as pop-corn for children, and it may possibly be made into bread, cakes, scones, porridge, etc., while whisky is often partially made from the same grain. On the other hand, it grew well in Spain, Italy, and France, and that its introduction into a country has always been followed by the appearance of pellagra in that country, and quotations supporting maize can be drawn even from the writings of its most vigorous opponent, Sambon, who states:—'From authentic documents of the time we learn that "melica," or "fromentone"' —*i.e.*, maize —'was grown in Cremona in the sixteenth century, and . . . in 1556 a Cremona nobleman offered the Duke of Florence ten *staia* of the new cereal.' When this statement that there is plenty of maize in Cremona in 1556 is compared with the statement that pellagra was well known in Cremona about 1700 to peasants and medical men alike, a Zeist would maintain that, allowing for the disease being so liable to be overlooked, this was a remarkable coincidence. Another epidemiological fact which, taken by itself, would strongly support the maize theory is the well-known fact that in the delta of the Nile there is plenty of pellagra and plenty of maize, but as the Nile is ascended the maize diminishes, millet being used instead, and the incidence of pellagra also diminishes and at present it is said to be unknown south of Assouan, which statement must be received with caution, as pellagra has so often been reported absent from places where it is now known: and, moreover, pellagra is known to exist in Central Africa. In Columbia pellagra is said to be found only in people who regularly take a drink made from fermented maize. This drink is called 'chicha' and the malady 'chichismo.' The Zeist states that pellagra is found wherever maize is used, at all events, as an important article of food. As a matter of fact, maize, either growing or imported, is found all over the world, and pellagra would appear also to be found all over the world.

Against the maize theory there are the facts that tend to demonstrate that persons who are alleged never to have tasted maize have suffered from pellagra: moreover, relapses have occurred after three, five, and even fifteen years' residence in gaols or asylums in which maize is not merely not allowed to be used as an article of diet, but care is taken, by inspection and by periodical chemical and microscopical examination, to exclude it. A Zeist would answer to these objections that there was some fallacy, and that nothing short of being the victim yourself would make it reasonably certain that maize was not consumed, and even then it might have been eaten unwittingly; and, further, that all safeguards designed to prevent food sophistications in institutions break down.

Notwithstanding this, some of the Scotch cases appear to exclude the possibility of maize being an ætiological factor, and prophylactic work on this basis has been so far a failure, for, although the disease has diminished in certain regions for a time, it has later returned with considerable vigour. With regard to the presence of pellagra in Europe before the introduction of maize there is no trustworthy evidence, and the possible occurrence of the disease in the celebrated St. Francis of Assisi is only an interesting speculation.

After carefully considering all the facts in support of the maize theory, and comparing them with those against, we have come to the opinion that the maize theory, *in general*, is so far based upon insufficient foundations. It is, however, necessary to lay before the reader the various phases of this theory, which may be classified as follows:—

1. Photodynamic theory.
2. Deficiency.
3. Toxicity.
4. Infectivity.

1. *Photodynamic Theory.*—The special promoter of this theory is Raubitschek, whose work has tended to show that an exclusive maize diet, good or bad, proves deleterious to white mice and guinea-pigs if these animals are exposed to sunlight. He also suggests that an exclusive diet of other cereals, such as rice, millet, or wheat, might, under similar circumstances, produce the same phenomena. This theory maintains that photodynamic substances are introduced by the cereals into the blood, and these, under the influence of sunlight, become toxins, and thus cause inflammation of the skin and other symptoms resembling to some extent pellagra. Moreover, Raubitschek maintains that he has cured mice suffering from fagopyrism by keeping them in darkness, even though the diet was unaltered, and, further, that he has obtained favourable results by excluding light from the skin of pellagrins by means of darkened rooms, red windows, ointments, bandages, etc. Hirschfelder has searched for this fluorescent (photodynamic) substance in the blood serum of five patients suffering from severe pellagra, and found that there was no difference in the fluorescence between their serum and that of healthy persons. Moreover, fagopyrism only occurs in white animals, and not in black; whereas pellagra can occur in the jet black negro, which appears to us to be a strong objection.

2. *Deficiency.*—This theory has been mentioned above with regard to the absence of nitrogenous complexes, and it only remains to add that protein deficiency has also been brought forward as a possible explanation of the action of maize in producing pellagra, but has no sound foundation. Moreover, many people live on rice and potato, which have lower nitrogen ratios than maize.

3. *Toxicity.*—Volpino, Mariani, Bordoni, and Alpago-Novello, have made investigations with regard to inoculating maize extracts into patients, obtaining several general reactions. These experiments support the latest view, which is really only the revival

of an older view, that normal maize in certain individuals may produce pellagra, or, in other words, that there is an individual susceptibility to maize. This subject has been recently carefully investigated by Rondoni in human beings. He procured his maize from the domestic store of certain pellagrins, and having tested his cases for tuberculosis by von Pirquet's test, administered extracts of the maize by intramuscular injections to thirty-three pellagrins and thirty non-pellagrins. He did not find any violent reaction, as described by other writers, but he found that recent cases of pellagra and convalescents reacted more definitely than non-pellagrins, showing slight fever, headache, malaise, excitability, and sleeplessness, and considered that this increased sensibility might be regarded as an anaphylactic reaction to some undefined factor in the maize extract. If this anaphylactic theory held, then any person who for a few weeks ate a quantity of maize at any time of the year should develop acute pellagra. The Illinois Commission attempted anaphylactic tests by von Pirquet's method, substituting maize extracts for tuberculin, and the result was negative.

A second theory states that pellagra is due to toxins produced during the spring by the germination of the maize. The objection to this is that some cases start in the autumn.

The third theory asserts that poisons are generated in the bowel from the grain (Neusser) by the aid of the *Bacillus coli communis* (De Giaxa). This latter theory of De Giaxa is supported by experiments, for he produced the symptoms in animals inoculated by the toxin produced by growing the *B. coli communis* in maize media.

Numerous observers have reported poisons in fermenting maize. Thus, Lombroso in 1871 obtained two alkaloids, one like conium and the other like strychnine, but the symptoms produced by these on men and animals were not like those of pellagra. Others have reported tetanic or narcotic poisons, etc., but, on the other hand, Monselice failed to obtain any such poisons in damaged grain from pellagrous districts.

4. *Infectivity.*—At the present time the popular belief is that the disease is caused by maize damaged by being cultivated and harvested under unfavourable circumstances, and stored in such a damp condition that it becomes mouldy. This has been supported by Hirsch, who points out that a bad maize harvest is followed by an increase in the cases of the disease. The theories as to the substance in the damaged maize which causes the disease are manifold, and may be classed into (*a*) fungi, (*b*) bacteria, (*c*) chemical substances.

(*a*) *Fungi.*—Monti and Tirelli showed that fungi were commonly found in maize, those most usually met with being ***Penicillium glaucum***, *Rhyzopus nigricans*, *Mucor racemosus*, and species of ***Aspergillus*** and *Saccharomyces*. The special fungus, ***Sporisorium maidis***, described by Ballardini in 1845 as the cause of the disease, is probably only ***Penicillium glaucum*** or ***Mucor racemosus***, the former being held by some writers to be the causative agent, but its effects on men and animals are quite different from pellagra. *Aspergillus fumigatus* and *Aspergillus flavescens* (or *A. varians*) have been obtained by Ceni in pure cultures from the lungs, pleura, and pericardium of pellagra cadavers, but the symptoms of the disease are quite different from aspergillosis. Later, Ceni and Fossati have stated that the real cause of the disease is the toxin from the fungi.

(*b*) *Bacteria.*—Monti and Tirelli showed that many bacilli grow in maize—*e.g.*, *Bacillus solanacearum*, and another like *B. subtilis*—and it has been shown by Paltauf that the so-called *B. maidis* of Majocchi and Cuboni is only the common potato bacillus. Another bacillus, called *B. pellagræ*, is stated by Carrarioli to produce toxins, which, when injected into animals, produce the typical symptoms of the disease.

Tizzoni has described a bacillus found in the cerebro-spinal fluid of pellagra patients and on maize, but this bacillus will be considered at greater length below.

The maize theory is therefore by no means proved, and in fact is, in our opinion, very doubtful.

Parasitic Theory.—The parasitic theory of the origin of pellagra, which is supported, to a certain extent, by our own observations and by the Illinois Commission, who conclude that it is a disease due to infection with some living organism, may be classified into:—

A. *Vegetal parasite.*
  Tizzoni's streptobacillus.

B. *Animal parasites.*
  Alessandrini's theory, 1910.
  Long's theory, 1910.
  Perroncito's theory, 1910.
  Babès' theory, 1911.
  Sambon's theory, 1905.

TIZZONI'S STREPTOBACILLUS.—This is really a part of the maize theory, as Tizzoni has found the bacillus on maize; but it is also a genuine parasitic theory, because he has also found it in the blood, cerebro-spinal fluid, and organs of pellagrins after death. He has found it in both acute and chronic pellagra; it is a non-spore-bearer, and resists temperatures of 80° and 90° C. for one hour. It is easily cultivated, and is believed to be taken into the body with the food, so causing the infection. Tizzoni claims that this organism is the cause of the disease, but this claim has been refuted by Wood, Raubitschek, the Illinois Pellagra Commission, and others, and therefore cannot be accepted as proven.

ALESSANDRINI'S THEORY.—From epidemiological researches mainly undertaken in Umbria, Alessandrini has come to the conclusion that there is some relationship between pellagra and drinking-water, and he has found a slender nematode worm in the drinking-water of pellagrous places. This worm, which he places in the family Filariidæ, he considers to be the cause of the disease. He also states that he has found a filarial egg in the skin of pellagrins.

According to Sambon, who has seen Alessandrini's specimens, the thick-shelled egg belongs to one of the nematode worms infecting pigs. Alessandrini's theory has not received much support up to date.

LONG'S THEORY.—This theory suggests that pellagra is merely a phase of amœbic dysentery, but the Illinois Commission, as well as the observations of Sambon and one of us, do not support this theory. Dysenteric-like ulcers can be found in the intestine, but they often do not contain amœbæ.

PERRONCITO'S THEORY.—Perroncito has found peculiar parasitic bodies in the skin of pellagrins. This is an important statement, and further investigation of these forms is awaited with interest.

BABÈS' THEORY.—Babès states that he has found bodies resembling a Chlamydozoon, in the skin.

SAMBON'S THEORY.—This theory is double-barrelled—*i.e.*, it brings forward the proposition that pellagra is a protozoan infection, and that it is spread by the agency of a biting fly.

Parasite.—His reasons for believing that it is a parasitic disease are almost entirely epidemiological. They are:—

1. *The Mononucleosis* present in the blood.

2. *The Presence of Long Intervals of Quiescence, followed by a Relapse.* Thus, a young pellagrin with marked symptoms who comes to London, and receives most excellent food, without any admixture of maize, suffers from a mild relapse every year in the month of April. In this case there can be no question of maize causing these relapses. Further, we may state that the young person appears to be in the very best of health at the time of writing (January). Similar, but not such convincing, cases have often been reported in gaols and asylums, as mentioned above.

Siler and Nichols in Peoria Asylum filled two cottages with about sixty insane persons in each. One cottage was placed on a generous maize diet and the other on a maize-free diet. At the end of twelve months the maize-eaters had four certain cases and one doubtful case of pellagra, while the maize-free group included five certain and five doubtful cases of pellagra. Probably these were merely relapses of the disease which had occurred long before, but as we have only seen a summary of the Illinois Pellagra Commission Report, we cannot give details.

A point has been made that, while patients in asylums develop acute symptoms, the attendants do not, and this is held to be an argument against the parasitic cause of the disease. But this is just where the experience of Sambon and one of us differs from those of many authorities, because we have seen the disease begin so often in early childhood. The youngest case seen was three months of age, and we have obtained excellent histories of long intervals occurring between one series of acute attacks and the next. We look upon these asylum cases as probably relapses of earlier attacks, and are therefore not surprised that attendants are not attacked, because probably the agent of the conveyance of the disease is not present in the vicinity of the asylum.

In other asylums, however, it is possible that, if suitable conditions were present, the disease might spread among the inmates and attendants.

3. *The Constant and Characteristic Topographical Distribution.*—We have already drawn attention to the topographical distribution, and to the fact that pellagra remains endemic in the same localities for very long periods, and we have also referred to the case of a young boy developing pellagra, though constantly residing in a town, after a brief visit to a pellagrous region. The case of the fishermen of Burano (*vide infra*) may also be quoted; and, finally, attention may be invited to many similar instances quoted by Sambon in his able 'Progress Report on the Investigation of Pellagra,' published in London in 1910. Associated with this, it may be mentioned that of two places almost contiguous one may be affected and the other not.

4. *Its symptoms, course, duration, morbid anatomy, as well as therapy, are similar to those found in parasitic diseases.*

5. *Spirochæte.*—Sambon found a spirochæte in the liquor from a bulla on the hand of a case of acute pellagrous dermatitis in Roumania.

These points will be dealt with under Pathology, and need not be discussed here.

Objections.—The principal objection to Sambon's theory is that up to the present no parasite has been definitely associated with the disease, but this may be at any time rectified in the near future.

The very few experiments performed on white rabbits, by injecting liquor cerebro-spinalis, blood from the erythema, or lymph from bullæ, subdermally or into the spinal canal, have produced no definite results, nor have attempts at intradermal inoculation of these animals with the same fluids been more successful. Neither have the attempts made by the Illinois Commission to transmit the disease to monkeys and guinea-pigs met with more success. Recently, however, Siler in a communication to Sambon has stated that injections of defibrinated blood taken from pellagrins have produced pellagra-like symptoms in monkeys.

In our opinion there is need for much more extended experiments, and we are supported in our belief by the finding of the Illinois Commission that '*Pellagra is a disease due to infection with some living organism.*'

Carrier.—Sambon, however, has not been content to remain with an incomplete theory, but has advanced the view that the disease is conveyed by some biting fly.

His reasons for this theory are:—

1. Pellagra is essentially a *disease of rural districts.*
2. It is in some way related to *moving water.*

3. It has a definite ***seasonal incidence***—spring and autumn—which coincides with the appearance of certain flies.

4. It largely affects ***field labourers*** and new residents in endemic areas.

5. It is ***not contagious***, and neither food nor water can account for its peculiar epidemiology.

6. In the endemic centres it ***affects all ages***, both sexes (as a rule, females are more frequently attacked than males).

7. An endemic centre is one in which it is usually easy to find ***young children*** with the symptoms of the disease.

8. In endemic centres ***whole families*** may show signs of the disease, but outside these only one or two individuals may be affected.

Researches on the Island of Burano in the Venetian Lagoon.—With regard to the theory of a biting fly, Sambon is supported by the inquiry into the pellagra of the Island of Burano made by himself, Colonel Belli, and one of us, in which it was found that the fishermen and the boys who went fishing with them, were attacked by the disease, while the men who worked in the Venice Arsenal were said by the medical authorities to be free from the disease. The women, the girls, and the young children showed no signs of pellagra, with the exception of two or three women, who gave a history of working on the mainland or on other islands adjoining. Many of these young children, girls, and even women, were alleged never to have moved from Burano, with the exception in some instances of an occasional visit to Venice. These points are contrary to the maize theory, as all the inhabitants in Burano eat maize. They are also against a hereditary transmission of the disease, for with pellagrous fathers it would be imagined that the young children should show signs of pellagra, especially as the male influence is said to be preponderant by those who believe in the heredity of pellagra. They are against sexual infection, as the women would acquire the disease; they are against infection by contact, by kissing, etc., because certain men and boys have the disease, but the women and girls are remarkably free; they are against a parasite being carried from the sick to the healthy by house parasites, such as bugs or fleas, or personal parasites, such as lice. The difference between the persons who suffered from pellagra in Burano and those who did not appeared to be the fact that the former either worked upon other islands or fished on the lagoon and up the streams leading into the lagoon. On the other islands and on ***terra-firma*** there are plenty of pellagrins, and everywhere there is a history of small black biting flies occurring on quiet days in the early morning or late evening.

Sambon considers that the peculiar feature of the erythema coming in the spring and the autumn must be a correlation with some insect, and considers that the Simuliidæ or some allied family would be the most likely to supply the requisite fly. He chose first the Simuliidæ because its larvæ lived in running water, and because it had two seasons, during which it appeared in swarms and attacked man and animals—viz., spring and autumn, and not in summer—a fact which we have been able to confirm for one of the regions which we visited.

The Illinois Commission and many others have been unable to support the relationship of pellagra to *Simulium.*

The epidemiological evidence in favour of the spread by a biting fly is, however, very strong.

Summary.—It appears to us that while at present the causation of pellagra is unknown, and while the modern tendency is to claim it as a deficiency disease, still the investigations of a possible protozoan parasite and its carrier should not be given up.

Predisposing Causes.—Sex would appear to be a predisposing cause, because the disease is often more prevalent in women than in men, and this would not appear to be so mysterious as it seems at first sight, for if there is anything in Sambon's fly theory, the women ought to be more exposed to the flies than the men, because they wash the clothes in the neighbouring streams. In one place where this incidence was most marked the men worked all day underground in mines, and the women presumably in and about the houses, which were on the banks of a fly-infested stream. Here the children also were much affected. In interesting contradistinction is the incidence in the women of Burano, who mostly work indoors and among whom pellagra was very rare; but it was common among the fishermen and boys who fish in the rivers, etc., where biting flies are common.

Age would not appear to have any marked influence, but it would seem as though the disease was very prevalent—in a mild form, at all events— in the early years of life, as the children of a pellagrous district are often early affected, and some of these attacks are by no means mild, but very severe.

With regard to social position, poverty, lack of sufficient food, and bad hygienic surroundings, it was long considered that these had a marked influence in producing the disease, but though they may help, as they would, with almost any form of disease, still, the American and our own experience show that they have no real connection with pellagra, which can equally well occur among the well-to-do, the well-fed, and those living in circumstances of good hygiene, though more commonly met with among the poor and those ill-fed and living in circumstances of bad hygiene.

There is a definite correlation between the lowering of the general resistance of the body against disease and an acute exacerbation of pellagra. Thus pregnancy, an attack of any illness, but especially enteric fever, may induce either an exacerbation or the first remembered attack of the disease.

Sunlight *per se* is not a causal factor, as far as we know, in the disease, but it is a powerful predisposing cause in helping to develop the dermatitis.

Pathology.—As the causation of pellagra is entirely unknown, the pathology must be purely speculative.

The *Zeists* see in the phenomena exhibited by the morbid anatomy and histopathology changes which appear to them allied to those found in scurvy, beri-beri, or ergotism, and believe that these changes support the maize theory.

The *Fagopyrists* see in the phenomena found in the skin lesions as well as in those of the rest of the body the signs and symptoms which can be produced in white animals fed on maize and exposed to sunlight, and believe that these changes support the photodynamic theory.

Those who support the *Parasitic Theory* quote the mononucleosis of the blood, the leptomeningitis, the perivascular infiltration, and the primary degeneration of the nerve cells, as well as the long intervals of apparent quiescence, as phenomena similar to those seen in syphilis and sleeping sickness, and therefore believe that these changes support the parasitic theory.

Sambon, however, has extended the parasitic theory by arguing that the erythemata appearing on the hands, feet, face, and neck, and more rarely on the genital organs, in the spring and autumn, are brought about by the combined action of the parasite, whatever it may be, and sunlight in correlation with the habits of some biting fly. From epidemiological studies he suggested that some member or members of the family Simuliidæ might be the insect in question. He came to this conclusion because of the known habits, life-history, etc., of the Simulidæ, which were in general agreement with the epidemiology of pellagra.

The reason why there is such a confusion of ideas with regard to the pathology is not difficult to understand, as a post-mortem made on a case of acute pellagra within an hour or so of death is of great rarity, and has often been performed under conditions of difficulty as regards cleanliness or preparation. Post-mortems on cases of recurrences or of chronic pellagra have been abundantly performed under the best auspices, but the main features of the disease are often obscured by secondary changes; while even in the acute cases the phenomena are complicated by the presence of malaria, typhoid, tuberculosis, syphilis, etc.

Notwithstanding all these objections, there is some evidence in favour of an early lesion of the central nervous system, especially the posterior portion of the spinal cord in the lower cervical and dorsal regions, as congestion and hæmorrhages have been found there, while in the more chronic condition degeneration of the cells in the posterior cornu, in Clarke's column, and in the spinal ganglia have been seen, as well as the later degeneration of some of their axones. Further, according to Brugia, acute degenerative changes can be seen in the cells of the sympathetic ganglia of the cervical and abdominal regions associated with a diffuse, round-celled infiltration of the interstitial tissue, which eventually leads to sclerosis. Degenerative changes have also been recorded in

Purkinje's cells, in the cerebellum, and in the cortical cerebral cells.

If these accounts are confirmed, they might be found to stand in relationship to the angio-neurotic process in the skin, the congestion of the alimentary canal, the vertigo, and the mental condition.

However, all these points are at present extremely obscure, and are only brought forward here because they appear to require investigation.

The lesions found in post-mortems in cases of acute pellagra, in our opinion, apparently support the theory of some protozoan parasite, as suggested above, acting upon the central nervous system and the autonomic nervous system.

Morbid Anatomy.—The principal point in studying the morbid anatomy of pellagra is to attempt to distinguish between the appearances truly produced by the disease and the signs caused by complications. As we are unacquainted with either the ætiology or the pathology of pellagra, this is most difficult, and only an attempt, which may possibly be fallacious, can be made.

The Essential Lesions.—Our experience would indicate that in *acute cases* the body need not be emaciated, and that no trace of the erythema may be visible, but that the lines of demarcation can, as a rule, be easily seen on the arms, legs, and neck, as well as the thickened or pigmented areas of the epidermis, bullæ, etc.

In these cases there may be fluid, and at times hæmorrhages under the cerebral dura mater, œdema and thickening of the pia-arachnoid, which, however, is not adherent to the cortex. The cerebro-spinal fluid is usually, but not always, increased in amount. In the cord there may be subdural hæmorrhages, sometimes extensive, especially in the region of the lower cervical and upper dorsal cords, and there may be congestion of that area of the cord; otherwise the naked-eye appearances of brain, spinal cord, and nerves, may be normal.

Sometimes the alimentary canal is almost normal, but this is rare, and usually there is more or less congestion and at times even ulceration of the mucosa of the small intestine, and the valves of Kerkring may show small hæmorrhages. The ileum may be thinned, and Peyer's patches may be diminished in number and atrophied (these lesions are, of course, found in many diseases). The large bowel may be thickened, congested, and ulcerated, but the ulcers need not contain amœbæ. Pancreas, liver, and kidneys may show signs of cirrhosis (the above intestinal lesions are often associated with polyfibrosis). The mesenteric glands may be enlarged, and congested. The spleen may or may not be slightly enlarged, and the suprarenal capsules may be larger than normal, and the cortex may be black, while the medulla is whitish in colour; but, on the other hand, the capsules may appear to be perfectly normal. In *chronic cases* the body is often emaciated and anæmic, the skin rough, hypertrophied in places and atrophied in others, the changes being marked on the face, neck, arms, hands, legs, and feet. The subcutaneous fat is diminished. The muscles, heart, liver, spleen, and kidneys, are all atrophied; the stomach is usually normal, but the intestines may be atrophied, as described above, and the rectum may be ulcerated. The nervous system shows a diffuse leptomeningitis, with marked thickening in places; the frontal convolutions may be atrophied in some cases and the motor convolutions in others. The bloodvessels may show calcareous degeneration, and there may be sclerosis of the postero-lateral and postero-median columns of the cord, and in the dorsal region there may be also lateral sclerosis. The posterior nerve roots may be implicated, and the intervertebral foramina may be narrowed by a firm cartilaginous-like deposit.

The Complicatory Lesions.—Very often in pellagra post-mortems the signs of secondary septicæmia (bacillary or streptococcal), of ankylostomiasis, of malaria, of enteric fever, of bacillary dysentery, of amœbic dysentery, and of tuberculosis, may be seen, and complicate the pathological picture. In performing post-mortems, it is necessary to attempt to unravel the true lesions from those caused by complications. The so-called characteristic intestinal lesions described above are met with in many post-mortems in which there is no sign of pellagra.

Histopathology.—With regard to the autonomic nervous system, the nerve cells of the sympathetic ganglia of the neck and abdomen are described by Brugia as becoming swollen, and showing chromatolysis, with changes in the nucleus and nucleolus in acute cases. Associated with this there is infiltration of the interstitial tissue and proliferation of the endothelial cells of the capillaries and circumscribed hæmorrhages.

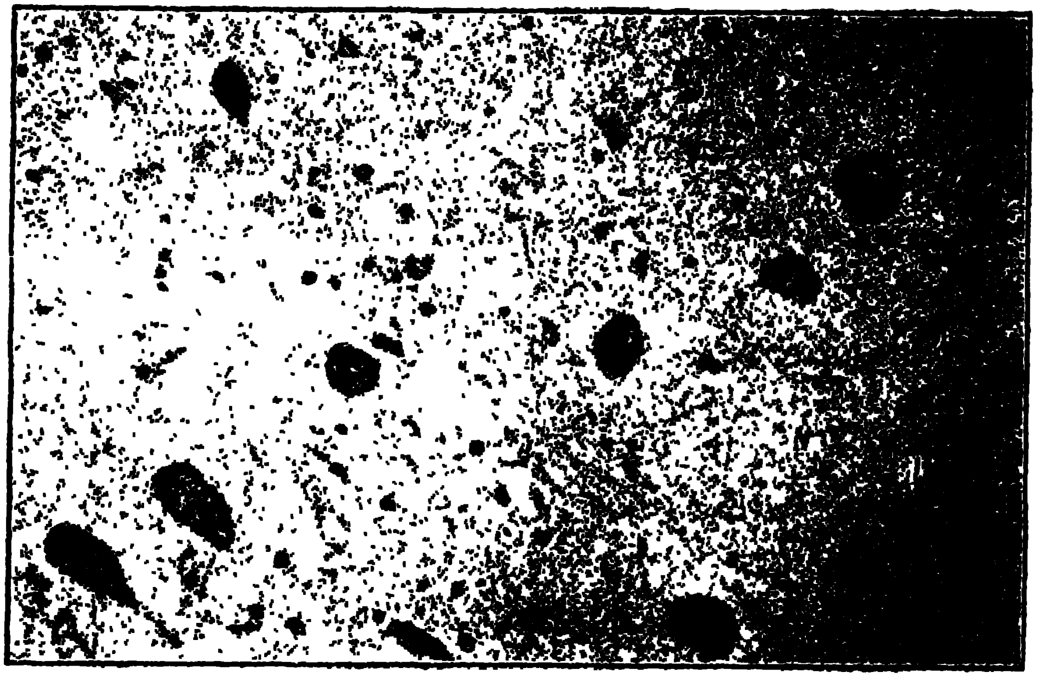

Fig. 738.—Cells of Clarke's Column in a Case of Acute Pellagra. (× 250.) (After Sambon and Chalmers.)

With regard to the chronic cases, there is atrophy and reduction in number of the nerve cells and sclerosis of the ganglion. The atrophied cells may be pigmented, but this is by no means constant.

In the spinal cord our own observations, as well as those of others, show that the posterior area is congested, and hæmorrhages are often present. Degeneration has been met with in the cells of the spinal ganglia, in those of the posterior cornu, and in those of Clarke's column. In these cells the Nissl bodies and the fibrils disappear, while the nucleus is placed excentrically, and often peripherally. Degenerated nerve fibres have been found in the posterior roots, in Lissauer's tract, in Burdach's column, and in Goll's column, and less commonly in the lateral columns. Some of the cells of the anterior cornu also degenerate. Degenerated nerve fibres may also be seen in the peripheral nerves.

In the brain the cortical cells have been found to be degenerated, swollen, and even disintegrated; while Purkinje's cells in the cerebellum are also said to degenerate. Mott has shown that while the fibrils surrounding these cells may be intact, those passing through the cells disappear. A perivascular infiltration around the vessels of the brain has been described by some authors, but was not present in our specimens nor in those described by Mott. There is also an increase in the neuroglia tissue in our specimens, but there is no cellular infiltration into grey or white matter, or any sign of acute inflammation.

The cerebro-spinal fluid is usually present in considerable quantity, and exhibits a medium amount of tension. It is alkaline, specific gravity varying from about 1004 to 1007; it generally gives reactions indicating the presence of some protein and butyric acid, and it generally reduces copper sulphate. The number of cells per cubic millimetre varies, but is about thirty-five, according to Hindman, whose differential count is: Small lymphocytes, 36·3 per cent.; polymorphonuclears, 18·6 per cent.; large mononuclears, 19·2 per cent.; plasma cells, 7 per cent.; lymphocytes, 5·1 per cent. The liquor is sterile, and injections into rabbits have been negative.

The skin has been reinvestigated by the Illinois Commission, who find that the changes can be described as due to an angio-neurotic process. There is infiltration of the true skin, and especially the pars papillaris, and œdema of the connective tissue. The rete Malpighii is infiltrated with cells, but otherwise normal. The stratum granulosum is normal, but the stratum corneum is thickened, and shows parakeratosis.

In the blood there is a reduction in the numbers of the red cells, which usually appear quite normal. There is mononucleosis, and Low has described granules in the mononuclear leucocytes, which, however, he has also found in other diseases. Fatty degeneration and cloudy swelling have been recorded in the liver, but no constant changes have so far been found in the spleen.

Symptomatology.—The incubation period of pellagra is unknown, but it cannot be of long duration, as we have known it to occur in a child three months of age, and, as we have already advanced arguments against heredity, this case is in favour of a short incubation period. We have also met with a case in which the skin symptoms are said to have appeared about two weeks after return from a visit to a pellagrous area in a person who was said to have always lived in a non-pellagrous area. We are always very sceptical of these histories, and should not have mentioned it if it had not curiously coincided with the case recorded by Sambon, where he states that a child born in an Italian gaol was nursed by its own mother in gaol until five months old, and then sent to some peasants living in a pellagrous area, when it developed pellagra in two weeks.

The description of a typical case is something of this nature:—A person, male or female, young or old, in apparently excellent health or in bad health; living or working in the sunshine of a spring day, notices that a sunburn appears on the backs of his hands, and perhaps the dorsa of his feet, if bare, and more rarely, also, on his face or neck. He thinks little of it, though the inflamed area burns, and may even blister. Perhaps he has a sore mouth, and perhaps he has a little diarrhœa or constipation. Perhaps he feels a little giddy in the morning, and perhaps he is easily tired. In a week or so the redness dies down, and the affected area is seen to be pigmented, and perhaps to have the skin thickened in places. In the course of a few days, or a week or so, these thickened areas desquamate, and the skin underneath may be found to be normal, or may be found to be slightly atrophic, and to appear whiter than the surrounding pigmented area.

The patient thinks no more of his troubles, the autumn comes, and he feels well, and during the winter there is no alteration in his good health. Perhaps the next spring may pass without a recurrence, and perhaps even several springs may elapse before the patient, who all this time may consider himself to be in excellent health, has a return of his symptoms. But though the interval may be long or short, this relapse will surely occur, and often it will be in a severer form than it was at first. It will usually recur in the spring, but it may take place in the autumn, or, much more rarely in our experience, in the summer.

This time the symptoms may be mild, as before, but, on the other hand, they may be severe: the erythema appears with severe burning sensations, and a real dermatitis, with bulla formation, may develop.

The tongue, lips, mucosa of the mouth and palate, may become inflamed, and show the presence of vesicles and ulcers. The parotid gland may enlarge (this is common in Egypt, but rare in other countries), the saliva may be so increased in amount that it pours from the mouth. There may be signs of dyspepsia, pains in the abdomen, and diarrhœa, or even dysentery may develop. The vertigo already mentioned

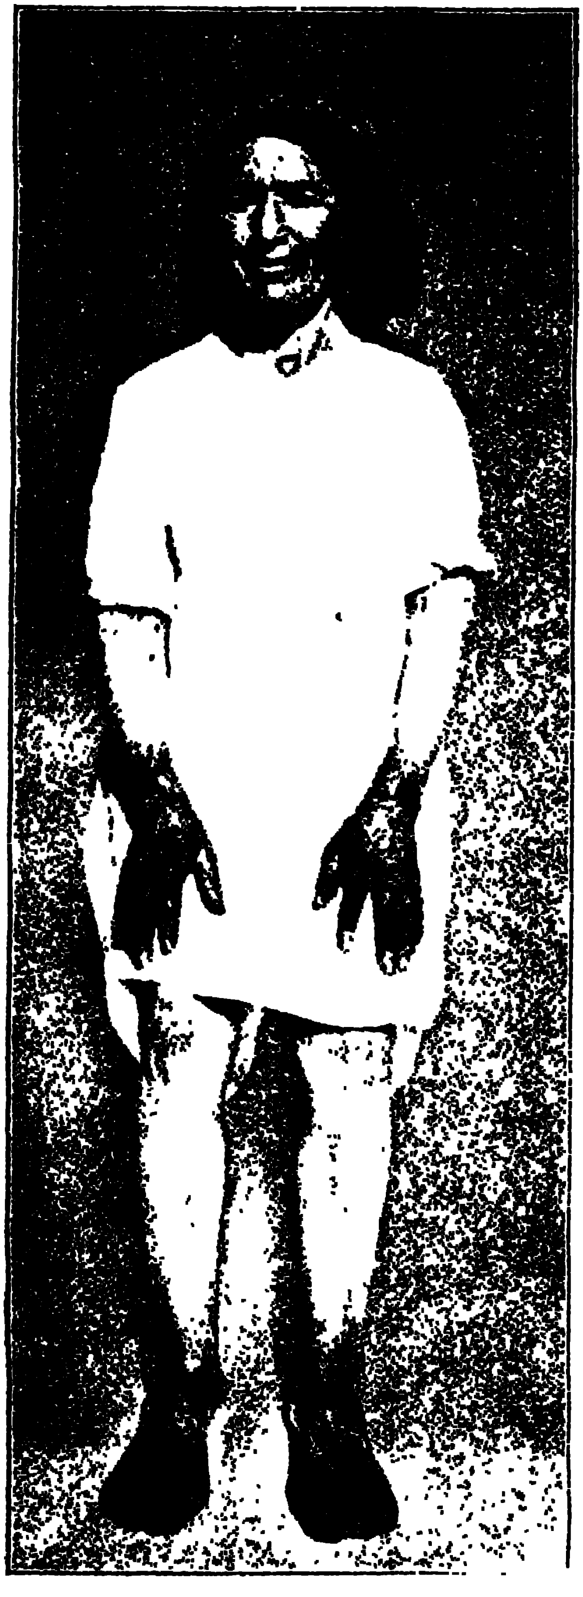

FIG. 739.—ACUTE EXACERBATION OF PELLAGRA.

Note the marked erythema on the hands and feet, and the less evident erythema on the neck and face.

(From a photograph by Terni.)

may become quite distressing to the patient, who, upon quickly rising from a sitting or a lying posture, may even fall to the ground. The muscular power may now be diminished, and the patient may no longer be able to do his work; tremblings in various parts of the body, but more especially in the head and arms, may be noticed, and the legs seem scarcely able to support the victim, who now shows decided melancholic symptoms, avoiding his fellows, becoming highly emotional, and perhaps threatening, or actually committing, suicide, often by drowning in water.

Pains are felt in various parts of the body, but especially in the head, the stomach, and the feet. A most unpleasant symptom is the burning sensation complained of by the patient after retiring to bed at night. So severe is this that patients have been known to strip off all their clothes and lie naked on their beds. By this time the unfortunate victim will have learnt by bitter experience that sunlight is deleterious to his condition, and will try to avoid it as much as possible.

Again, as winter approaches, the symptoms will diminish and die away, and the patient will feel better; but this time the skin does not recover itself, but remains thickened and pigmented in places, and thinned, whitened, and atrophic in other places.

Again, there may be only an interval till the next spring or autumn, or the succeeding spring, or there may be a longer interval, and again mild or severe symptoms may appear.

With repeated attacks the skin changes become marked, the mind becomes often permanently affected, and melancholic or maniacal symptoms are often observed.

Pain is often complained of in the back, and tenderness is found on pressure over the spinal nerves on either side of the dorsal or lumbar portions of the vertebral column. Muscular weakness is noted, especially in the legs. The knee-jerk is at first exaggerated, but later is diminished, and finally lost. Ankle clonus and wrist clonus are rare, and only occur when the knee-jerk is exaggerated, when there is tenderness on both sides of the dorsal and lumbar cord, and when abdominal and epigastric reflexes are also increased.

There is no special gait, but there is a tendency to fall backwards or forwards, and hence, though the patient walks with the legs well apart, in a very bad case he can only take a few steps without falling down. There may be tremors in the legs and tongue. The bladder and rectum are not as a rule affected until the end, but there are exceptions to this, and contraction of the limbs does not take place till bedridden; but moderate rigidity of the muscles of the arms and legs, associated with stiff and at times irregular spasmodic movements, has been recorded as occurring early in rare acute cases. A sudden rigidity of the body associated with retraction of the head has also been observed. These attacks last only a short time, but are recurrent. Trophic lesions, such as bedsores, are of rare occurrence. Hyperæsthesia may occur in different parts of the body, and pains (even of a lightning nature) may exist in the head and back, and be associated with cramps.

The facies of the pellagra patient is one of anxiety and mental worry. He cannot sleep, and there is often great mental depression and discontent; but some are excitable and irritable, while others are stupid and morose. He loses his memory, and has vague feelings of pressure, weight, or pulsation about his head. From this he proceeds to refusal of food and suicidal tendencies, with delusions of sorcery and persecution, and has a tendency to suicide by drowning. Melancholia may now become confirmed, and may eventually pass into dementia.

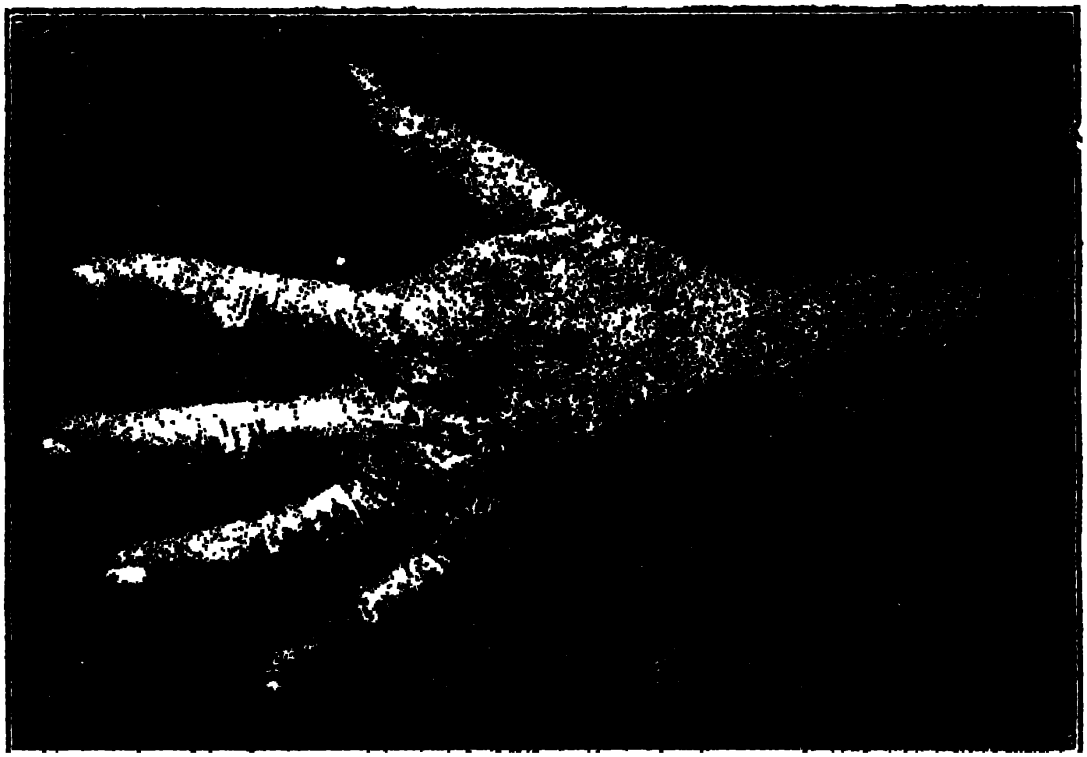

Fig. 740.—Hand in Chronic Pellagra.
(From a photograph by Sambon and Chalmers.)

Various paralyses develop, such as spastic paralysis, ptosis, hemianopsia, diplopia, amblyopia, and mydriasis. The extremities and bladder now become paralyzed, and the demented, paralyzed, rapidly emaciating patient, suffering from bad sweats, profuse diarrhœa, and sometimes dropsy, obtains a relief from his sufferings in death, the disease has usually lasted from ten to fifteen years.

Such is a general account of this rather protean disease, and we note that there is an onset in the spring, or more rarely in the autumn or summer, an intermission in the winter, and a relapse in the next or some following spring or autumn.

Very rarely a case of pellagra may be acute, lasting only a few months.

Children.—The disease is so common among young children in bad pellagrous districts, and so often can one, by careful inquiry, elicit curious facts that tend to show that pellagra, though occurring in the person in question in adult life, probably really began in infancy, that we are inclined to believe that the cases in young children are often overlooked, and we are supported in this belief by the mildness of the symptoms which we have observed in some children, which indicate merely a sunburn on the face, hands, arms, feet, legs, and perhaps the neck, associated with a little diarrhœa or constipation. The child recovers, the skin becomes normal, the attack is forgotten, and does not return until adult life, when the patient may have grown up and been living for years in a town, when a typical relapse appears—a new case (a town case it would be classified by many authors), but a careful inquiry into the history of the case may elicit the fact from intelligent people that the first attack began in childhood, when it may be explained by the friends as being in reality a sequela of Jenner's vaccination.

F 741.—HAND IN CHRONIC PELL.

Note the thickening of the epidermis and the line of demarcation. The hands in both figures had been vigorously scrubbed by the patient to try to remove the scabs.

(From a photograph by Sambon and Chalmers.)

Inquiry may often elicit the fact that when this occurred the patient, at that time a child, was living in the country, and often in close proximity to a stream—a fact which may be confirmed by a visit to the locality.

Another curious point with regard to some of these early cases is the history given by the friends of the development of some extraordinary habit of dietary, to the influence of which the disease is often assigned. These extraordinary cravings appear to us to be due to the dyspepsia (hypochlorhydria) so commonly met with in pellagrins.

We have rather insisted upon the occurrence of pellagra in young children because we are of the opinion that it is often overlooked.

Skin Eruption.—The skin eruption is usually limited to the regions exposed, being at first delineated in a most exact manner by the clothing: but in very rare cases it may be universal, and it is said sometimes to appear limited, as though by clothing, in naked gipsy children. It appears on the dorsum of the forearms, and on the hands and feet, only reaching the flexor aspect after several attacks. The most common sites are the hands and forearms, elbows, feet, legs and knees, the upper part of the chest, the shoulders, neck, and face. More rarely it appears on the genital organs and around the anus in both sexes. Sandwith points out that in Egyptian peasants the ungual phalanx of the hand is seldom affected, due to the fact that when the hoe is grasped it is protected against the sun's rays. The nails and hair are not affected, but rarely there is a dry, scaly condition of the palms of the hands.

The skin eruption may show the following conditions:— (1) Congestion: (2) inflammation: (3) thickening and pigmentation; (4) atrophic thinning.

The affected part turns a bright, dark, or livid red colour, which at first disappears on pressure, and is generally delineated by a very clearly raised limiting line. Associated with this erythema there is a burning sensation, but usually no pain. In course of time the part becomes swollen and tense, and bullæ may form. After lasting a variable period of days or weeks, the eruption gradually subsides, leaving the skin rough, pigmented, and thickened, and thus earning the names of 'pell'agra' and 'qushuf.'

This erythema disappears in the winter, but reappears the next spring with increased virulence, and in due course develops into a dermatitis, which produces an exfoliation of the epidermis in grey or brown flakes. Every attack leaves the affected area a little more pigmented, a little more thickened, and a little less elastic.

After lasting about four or five years the skin begins to atrophy, and becomes wrinkled and inelastic. This atrophy is most marked on the back, hands, and feet. Special terms have been given to the eruption when in certain areas—*e.g.*, the 'glove,' the 'boot,' Casall's 'necklace,' or 'cravat,' and the 'mask.'

Roberts has introduced the rather useful term 'dermotagra' for the dry, scaly, thickened skin seen over the olecranon process, over the knees, and more rarely on the palms of the hands. Over the elbow and knee the skin is rough, thickened, and wrinkled; on the palms of the hands it is merely rough and thickened.

Another interesting dermatological feature of pellagra is the frequency of nasal or facial seborrhœa, which is to be especially noted in the nose where the sebaceous follicles are very prominent and filled with plugs of sebaceous material.

The Mouth.—The tongue is generally coated with a whitish fur during the onset of an attack, but later it becomes abnormally clean—'*Sandwith's bald tongue*'—red, swollen, and sometimes ulcerated near the tip. It may also become fissured, but in mild cases it recovers as soon as the attack is over.

During attacks the gums may become spongy, and may bleed, and ulceration may appear, both here and on the palate, as well as on the pillars of the fauces. There may be pharyngitis, and more rarely œsophagitis.

The Blood.—The red cells are usually reduced in number, and the hæmoglobin proportionally reduced. Usually the form of the red cells is normal, but microcytes, and more rarely megalocytes, may be found. There is usually only a slight leucocytosis in uncomplicated cases, but there is in our experience generally a distinct mononucleosis. When the polymorphonuclear cells are increased, it would appear to always indicate a complication.

Circulatory Organs.—The blood-pressure is usually low, and the heart-rate may be markedly increased. Vasomotor changes can be observed in the coldness of the extremities, the bluish congestion of the feet and hands, the goose skin, and the neuroparalytic dilatation of the vessels of the face often giving rise to an appearance seen in alcoholics.

Respiratory Organs, etc.—The respiratory organs are not affected in pellagra unless there is some complication, but there may be an exudation of fluid into the pleural cavities in the late stages of the disease, as well as œdema of the bases of the lungs.

Urinary Organs.—Usually the urine is normal, or nearly so, and any great change must be considered to be a complication.

Sexual Organs.—Sexual power is usually diminished, especially in the later stages. Amenorrhœa, metrorrhagia, and inflammatory conditions of the vagina, uterus, ovaries, etc., are described, but must be considered as complications.

Special Senses.—The eyes suffer most in pellagra, but the changes—*e.g.*, weakness of vision, photophobia, etc.—are not dependent upon the disease *per se*, but upon the weakness which it produces. The patients often complain of a saltish taste in the mouth.

Fever.—As a rule the temperature is but little altered from normal in pellagra, but it may be raised at intervals as high as 101° to 102° F. (Wood) for two to three days at a time, but it may also be subnormal in other cases.

Complications.—As may be imagined, in a disease of such long duration as pellagra, the complications are numerous, and include malaria, tuberculosis, ankylostomiasis, bilharziosis, eye affections, and many skin diseases, including itch.

The most interesting complication is enteric fever, which may give rise to the form often called 'typho-pellagra,' which is apparently simply a pellagrin with an infection with one or more of the organisms causing enteric fever.

Terminal infections with various micro-organisms have been noted, and complicate the post-mortem findings. Thus, Bon records the occurrence of *Streptococcus pyogenes* in the blood as found by examination immediately after death.

Diagnosis.—Everywhere since pellagra was first recognized there has been great difficulty in its diagnosis, and it would appear necessary to consider not merely the signs exhibited by the patient, but the frame of mind in the observer in attempting to write upon this subject.

For the diagnosis of pellagra two conditions are necessary in the observer. The first is that he must suspect its presence, and be on the outlook for it in any and every country; and the second is that he must not be unduly swayed by any ætiological theory, and must be prepared to make a diagnosis of pellagra in a person of any age, any race, any social condition, living in any place, whether tropical, temperate, or frigid; resident in a town or in the country; and he must do this without consideration of the dietary or the surroundings, with perhaps the sole exception of being more intently awake to the possible occurrence of the disease in lunatic asylums.

As there are at present no microscopical, bacteriological, parasitological, hæmatological, or chemical reactions which can be said to be diagnostic of the disease, with, perhaps, the sole exception of the pellagra-like symptoms produced by one of the American Commissions, by injecting defibrinated blood into monkeys, and as these animal injections are not within the range of practical politics for purposes of diagnosis, we must trust entirely to clinical manifestations.

The cardinal signs of the disease may be summarized into—(1) *the cutaneous signs*, (2) *the gastro-intestinal signs*, and (3) *the nervous signs*.

In order to make a definite diagnosis, there must be either the presence or a definite history of the cutaneous signs of pellagra associated with symptoms belonging to one of the other groups.

1. *Cutaneous Signs.*—When a person shows more or less symmetrical erythema, dermatitis, pigmentation, or a condition more or less resembling chronic dry eczema on either the backs of the hands, the dorsa of the feet, the face, the back and sides of the neck, or the front of the chest, especially if these eruptions are limited by a more or less definite elevated margin to the areas habitually exposed to light, suspicion should at once be aroused that the disease is pellagra. If a history can be obtained that this eruption appeared for the first time in spring or autumn, and more especially if a history of recurring attacks can be obtained, the suspicion becomes almost a certainty. If to these signs there are added the fact that the skin symptoms become worse on exposure to the sun, or that there are at the same time disturbances of the

alimentary canal or of the nervous system, and especially if there is the presence or the history of *vertigo*, then the diagnosis is certain.

2. *Gastro-Intestinal Signs.*—Gastro-intestinal symptoms are usually present, but they may be extremely mild, and they may be absent. Those most commonly met with during exacerbations are—Salivation, stomatitis, dyspepsia due to hypochlorhydria, diarrhœa, dysenteric symptoms, alternating with constipation, or simply constipation appearing or recurring in the spring or autumn. A diagnosis cannot be made by these symptoms alone, which must be considered in conjunction with the cutaneous in order to arrive at a conclusion. If no cutaneous symptoms are visible, it is justifiable to place the patient in strong sunlight in order to see whether the dermatitis will appear.

3. *Nervous Symptoms.*—Of all the nervous symptoms early exhibited, the vertigo is the most common, and should be carefully inquired for, as the patient often does not associate slight morning vertigo with the disease, and will therefore omit to mention the fact.

Other important symptoms are the melancholia, the myasthenia, the tremblings, and often curious delusions, and the irritable condition of the temper, recurring in the spring or autumn; but these must be associated with evidence of skin lesions before a diagnosis can be made.

It will thus be observed that, while the diagnosis may be a matter of extreme simplicity in a typical case, it may also be one of great difficulty in atypical cases. Perhaps the greatest difficulty is met with in lunatics and young children.

1. *Lunatics.*—In these cases the patient has been admitted into the asylum suffering from one of the well-known forms of mental disease, but most probably from melancholia or dementia, more rarely from attacks of mania. It may be noted that at times he suffers from diarrhœa or dysentery, which is often assigned to what used to be called 'lunatic asylum diarrhœa' or 'dysentery.' It may also be noted that at times he spits considerably, which simply means that he has an excess of saliva; but, much more importantly, it is noticed that he suffers from *chronic eczema* on the back of his hands, from *angioneurotic œdema* so called, both of which are often common in lunatics. Such cases require careful investigation, not with a view of making a diagnosis of pellagra, but with a view of excluding, if possible, the diagnosis that the case is really pellagra.

2. *Young Children.*—In young children the disease is very apt to be overlooked, and the red eruption on the face and hands, etc., followed by pigmentation, is generally attributed to sunburn or to eczema, while the alimentary disturbance is assigned to infantile gastro-intestinal derangements, and not connected with the skin lesions. A careful inquiry will show whether these symptoms have or have not a seasonal incidence, and in any case they should arouse suspicion of pellagra, which should only be eliminated after careful inquiry.

Differential Diagnosis.—As the symptoms are divisible into three groups, so the discussion of the differential diagnosis is equally capable of arrangement under the same three headings.

SKIN DISEASES.—The skin diseases which are to be differentiated from pellagra are classifiable into those resembling the acute cutaneous symptoms and those resembling the chronic cutaneous appearances.

1. *Resembling the Acute Dermatitis.*—Under this heading comes, first of all, *erythema solare*, from which pellagra may be distinguished by the inflammation of the mouth, by the presence of the alimentary canal symptoms, and by the vertigo, as well as by the fact that the pellagrous eruption at times appears on parts not usually exposed to the sun, and by the fact that the lesions in sunburn are usually very superficial.

The same diagnostic points will help to differentiate pellagrous dermatitis from *erythema* or eczema due to winds, salt air, etc.

The erythema on the face, hands, arms, etc., in cases of *dermatitis venenata* may simulate pellagra closely. The pellagrous condition may be differentiated by the presence of gastro-intestinal nervous symptoms, by the less general extension of the eruption, by the less involvement of the eyelids, and by the more acute course.

From *acarine dermatitis* pellagra may be distinguished by the localization of the eruption, which does not appear on the trunk, by the absence of the vesiculo-papules and pustules, and by the absence of itching.

From *alcoholic erythemata* it may be recognized by the history of the attack and by the presence of the typical eruption on the hands and feet.

Some authorities have, however, described, under the term *pseudo-pellagra*, of alcoholic origin, an erythematous eruption on the hands associated with nervous symptoms which is indistinguishable from true pellagra, being, in fact, the same disease.

From *angioneurotic œdema* it may be differentiated by the absence of marked œdema and the presence of more inflammation in the skin, as well as by the more regular distribution of the eruption, and by the limiting line.

2. *Resembling the Chronic Dermatitis.*—From *chronic eczema* occurring in mentally sound persons or in lunatics pellagra is recognized by the typical distribution of the eruption, by the line of demarcation, and by the marked pigmentation, when present, and absence of pruritus. From *chronic syphilides* by the distribution of the eruption, and by the absence of any reaction to mercury. Here mention may again be made of the *dermotagra* on the palms of the hands, over the olecranon, and about the knee, in chronic cases of pellagra, which is apt to be overlooked, or to be considered as points in favour of a diagnosis of eczema rather than of pellagra.

From biotripsis (*vide* p. 2282), which it closely resembles, pellagra is differentiated by the limitation of the eruption to the areas so often mentioned above, by the presence of the line of demarcation. In biotripsis the skin is dry and wrinkled, and may be thickened in places with dark-coloured patches, alternating with shining, smooth, inelastic, atrophic areas; but this condition is by no means limited to the hands or feet, but spreads up the arms and legs, and is not visible on the face.

It is hardly possible that *Kaposi's disease* (xerodermia pigmentosa) could be mistaken for pellagra, nor is *ichthyosis* likely to be confounded with it.

The wrinkled skin of the *washerwoman's fingers* is hardly likely to be confused with the chronic thickening found in pellagra, though this disease is often found in women who wash clothes, and who explain their own dermal condition in this way.

GASTRO-INTESTINAL DISEASES.—Of all the gastro-intestinal diseases, *sprue* is the only one which in any way resembles pellagra, which can be readily distinguished therefrom by the presence of the skin eruption. It must, however, be remembered that the psilosis linguæ pigmentosæ of West Indian writers is really pellagra.

Attacks of *diarrhœa* or *dysenteric-like attacks* can only be recognized as belonging to the syndrome of pellagra if the dermal signs are present at the same time, or if they can be produced by exposure to the sun, or if there is a very definite history of their previous occurrence; unless, indeed, they are associated with marked ptyalism or bilateral swelling of the parotid glands, or some other symptom tending to indicate that pellagra was the cause. The special cases in which diarrhœa and dysentery require careful diagnosis are those in which they occur in lunatics.

TYPHO-PELLAGRA.—In this disease the dermal signs of pellagra are sufficiently evident to enable its diagnosis to be made, as a rule, without difficulty, while the diagnosis of typhoid fever can be made by the methods already described on pp. 1389-1394.

NERVOUS DISEASES.—Melancholia, dementia, mania, etc., can only be diagnosed as pellagrous when associated with its skin lesions; but here care must be taken not to mistake the dermal signs of pellagra for chronic eczema, etc.; but this point, having been already discussed above, need not again be argued.

Prognosis.—This would appear to be good in early cases in mild cases, and even in moderately severe cases, if the patient can be removed from the pellagrous area and placed in good condition of food and hygiene in a non-pellagrous area.

But predictions as to a cure must be guarded, and it must be remembered that cases have relapsed after two, five, and even fifteen, years' intervals.

In severe cases the prognosis must be guarded, and the low blood-pressure remembered, as well as the possibility of sudden death from exertion after lying down.

Cases of typho-pellagra have a high mortality, and here the prognosis is obviously bad.

Complication with ankylostomiasis, tuberculosis, etc., also render the prognosis more unfavourable, as does continued residence in a pellagrous area.

Treatment.—There can be no doubt that the essential basis of the treatment of pellagra is to remove the patient from the pellagrous area in which he has been living to a non-pellagrous area; and, secondly, to give a good and liberal diet, preferably without any admixture of maize, although Devoto has shown that good maize not merely does no harm to pellagrins, but is very suitable for some of them, as it is their usual diet. If this is done, most early cases quickly improve, and apparently are cured, but, unfortunately, this is not so, because, even if they remain under these excellent conditions, sooner or later a recrudescence occurs. These recrudescences may be mild, but at any time they may become severe, even when maize is excluded from the dietary.

Arsenic.—This being so, it is obvious that some medicinal treatment is necessary, in addition to change of locality and diet, and apparently the best remedy is arsenic in some form. Of all forms of the drug, that most commonly in use, and also much vaunted, is 'atoxyl,' which is administered by intramuscular injection of 3 grains per diem.

Other methods of giving arsenic are salvarsan, neosalvarsan, and soamin.

Other methods are the cacodylate of sodium, administered in 3-grain doses by intramuscular injection every third day until three doses have been given, and then every second day until three more doses have been administered, and then increasing to 5-grain doses every second day until the symptoms have improved.

Associated with these injections, it is as well to give liquor arsenicalis in small doses internally, and to continue this interruptedly for some three months after the symptoms have disappeared. In addition, it is as well to repeat the liquor arsenicalis some weeks before the advent of spring, and to continue it intermittently into the summer for a few years after an attack, in order to attempt to guard against the almost inevitable relapse.

Radio-Active Serum.—Nicolaidi has devised an artificial organo-mineralized radio-active serum from horse serum, together with all the organic and mineral salts of the blood, in a solution saturated with carbon dioxide gas, which was then rendered radio-active. This serum is administered by injections until twenty to twenty-five are given, when, according to the author, supported by several eminent authorities, most remarkable improvement in the cases resulted.

Symptomatic Treatment.—The patients must be protected from the sunlight by clothing, veils, hats, gloves, etc., and the dermatitis must be treated by emollient lotions, such as calamine, soothing and dark ointments, such as ichthyol in lanoline.

The indigestion should be treated by a mixture containing dilute hydrochloric acid and infusion of gentian.

The diarrhœa and dysentery should be treated as indicated on p. 1854 for bacillary, or on p. 1834 for amœbic, dysentery.

With regard to the nervous symptoms, the irritation on retiring to bed and the sleeplessness should be remembered, and combated with cool bathing, and, when necessary, by doses of bromides, which, however, are apt to increase the depression.

The vertigo should be borne in mind, and precautions taken to prevent accidents being caused by it.

The mental condition should be cheered by pleasant surroundings, and in severe cases a watch taken to prevent the suicidal tendencies taking action.

Diet.—The diet must vary with the condition of the digestion and the bowels, and during attacks of dysentery or diarrhœa that laid down on p. 1858 should be adopted.

Complications.—Search should be made for signs of ankylostomiasis, ascariasis, etc., tuberculosis, malaria, etc., and these should receive their appropriate treatment.

Typho Pellagra.—This serious complication, which is really only an attack of enteric fever in a pellagrin in whom the acute symptoms at once become aggravated, must be treated by a combination of the treatments laid down for enteric fever on p. 1309, and pellagra, as above.

Prophylaxis.—As the ætiology of pellagra is unknown, it is obvious that remarks as to prophylaxis must be more or less speculative. It does not appear to be directly contagious, and therefore isolation, quarantine, etc., appear to be useless. In accordance with certain ætiological views, it is advisable to attempt to avoid being bitten by flies in the early morning or late evening in the endemic areas by the use of protective veils, fly-brushes, etc. Protection against the sun, as described above, is also of great importance.

It is obvious that the consumption of diseased or damaged maize must be injurious, and the action taken by the Italian Government to prevent the sale of bad maize is not merely highly commendable, but must be most beneficial to the community at large.

Further, the excellent attempt to find out every pellagrin by means of local lists is good, as it enables the Government to know exactly the condition of this dreadful malady, provided the lists are carefully compiled; on the other hand, if these lists are inaccurate, they may result in much misconception of the incidence of the disease. The provision of one good meal a day to poor pellagrins during the spring and autumn is, in our opinion, highly to be praised. That these meals are good, we can certify from personal experience. We fail, however, to see the utility of the free distribution of salt, but it does no harm.

The methods adopted by the Italian and other Governments may be summarized as follows:—

1. *Laws and Regulations.*

(*a*) **Prohibiting the importation and sale of spoiled corn.**

(*b*) **Government inspection of all corn dried, stored, or consumed. This includes the erection of public storehouses.**

(*c*) **Provision of desiccating plants to dry corn.**

(*d*) Cases of pellagra to be reported, and lists to be kept and emended every year. Unfortunately, they are not always very accurate.

(*e*) Formation of *locande sanitarie*—*i.e.*, kitchens where excellent free meals are given to pellagrins, and, it is to be hoped, to other deserving poor people also.

(*f*) Free distribution of 17½ pounds of salt to every adult pellagrin and 11 pounds of salt to every child pellagrin per annum. This distribution is arranged by a ticket system.

(*g*) Establishment and upkeep of *pellagrosaria*—*i.e.*, special hospitals for the treatment of pellagrins

(*h*) Establishment of *pellagrological commissions* in every province affected with pellagra, with powers to work the laws and to investigate the disease.

(*i*) Financial supply.

2. *Formation of Rural Bakeries.*

Model central bakehouse, controlled by Government, in which the only bread allowed to be used is baked from good, wholesome wheat-flour. The best model we have seen was in the Tyrol.

3. *Improvement of Agriculture.*

(*a*) By *cattedre ambulanti*, or farmers' institutes, designed to teach *locally* modern methods of agriculture, with the result that the farmers become less poverty-stricken.

(*b*) Advising the farmers no longer to plant second crops of inferior qualities of maize, called *quarantino* (*Zea mais v. præcox*) and *cinquantino* (*Z. mais v. subpræcox*), which, being gathered in the wet month of October, were often only half-ripe, and soon decayed.

(*c*) By organizing *agricultural shows*, which include the exhibition of *maize*.

REFERENCES.

The most useful reference is Salveraglio (1887), *Giornale della Società Italiana d'Igiene*, Milano, whose paper of 150 pages, entitled 'Bibliographia della Pellagra,' contains a list of the articles published up to 1887. Lavinder and Babcock's translation of Marie's 'La Pellagra' brings the literature in English up to 1910. The most useful journals are the *Rivista Pellagrologica*, published in Udine; the *Tropical Diseases Bulletin*, published in London; while the Atti dei Congressi Pellagrologici and the Reports of the Triennial Meetings of the American Society for the Study of Pellagra also contain valuable information. A very valuable series of papers is to be found in the publications of the United States Senate, and also in the United States Public Health Reports, and in the Transactions of the Society of Tropical Medicine, London.

DISEASES OF THE MOUTH, THROAT, AND STOMACH

General remarks—Oral infections—Thrush—Gingivitis—Lingual affections—Halzoun—Tonsillar affections—Gastric diseases—Earth-eating—Belyando spew—Entalação—References.

GENERAL REMARKS.

In this chapter we make some remarks concerning the diseases of the mouth and the stomach, which we will preface with a few general statements concerning the intestines, as this is the most convenient place for so doing, though we describe the more important diseases of these parts of the alimentary canal in separate chapters.

External hernia is common, but internal hernia is rare: we have only met with one example, and then of a most unusual form, the displacement being through a rupture in the transverse mesocolon, forming a hernia into the lesser sac. This hernia probably took place through the recessus intermesocolicus transversus (Bröscke). *Intussusception* and *volvulus* are known, as well as intestinal obstruction due to bands, and we have met with one unique case of fatal intestinal obstruction in a native found dead, caused by the compression of the rectum against the pelvic wall by an enormously distended bladder, which we had not thought to be possible.

Cancer of the bowels is by no means uncommon. *Tuberculosis* of the bowel is generally secondary to tuberculosis in some other regions, but we have seen primary tuberculosis. *Appendicitis* is quite common in both Europeans and natives, and is caused by bacteria acting either directly, or introduced by the action of *Trichuris* and *Ascaris*. Appendicitis of schistosomic origin has been recorded by Mursell.

In previous editions we called attention to the frequency of *intestinal sand*. The true intestinal sand of animal origin composed of dark grey or colourless gritty particles, and largely composed of lime salts, is occasionally met with, but far more common is the so-called *pseudo-intestinal sand* composed of undigested remains of vegetable food (bananas, etc.), which may become encrusted with earthy salts. Delgado Palacios has called the condition 'fæcal sarcoma.' In these cases there may be diarrhœa and colicky pains.

Uronema caudatum has been recorded by Fischer, in 1914, in the diarrhœic stool of a European in Shanghai. Two days later only cysts were present.

ORAL INFECTIONS.

The protozoal parasites reported as being found in the mouth are:—

Loeschia gingivalis Gros.
Leishmania tropica Wright, var. *americana* Laveran and Nattan-Larrier.
Spiroschaudinnia dentium Miller, and many other spirochætes.
Spiroschaudinnia buccalis Steinberg.
Treponema mucosum Noguchi.
Treponema macrodentium Noguchi.
Treponema microdentium Noguchi.

Flagellates have also been recorded.

Gongylonema pulchrum.—This filarial worm is a parasite of the pig in Europe and America, but was described, in 1916, by Ward as occurring in the lower lip of a girl, aged sixteen years, at Jefferson in Arkansas. The worm was 42·1 millimetres in length, and tapered slightly at each extremity, of which the anterior was ornamental, by a system of cuticular tubercles, while a cuticular ridge ran along the lateral line.

The most common and perhaps most serious affection is *Pyorrhœa alveolaris*, in which condition pus wells up from alongside the roots of the teeth, while the gums become swollen, reddish, and inflamed, the teeth loose, and general septic absorption or infection may result.

The organisms associated with this lesion are innumerable—amœbæ, spirochætes, bacteria, etc.—and, therefore, the causal germ is unknown, but the treatment is quite clear—viz., to remove all teeth which are too far decayed to allow any hope of improvement, or which are viewed as dangerous from a general health point of view. Having done this, the next and most important point is *ionization* with zinc sulphate.

Apart from this, all bridges, crowns, and fillings have to be viewed with suspicion in the tropics, and vague septic conditions, diarrhœal or even dysenteric-like symptoms, and more especially inflammatory changes about the jaw, should lead to careful examination of teeth treated in this manner.

It will be remembered that streptococci are apt to enter the system alongside the teeth and via the tonsils, and, therefore, the streptococcal infection should be thoroughly and carefully treated.

The *inflammations of the tonsils*, diphtheritic, pseudodiphtheritic, and streptococcal, are common in the tropics, though diphtheria is somewhat rarer than in temperate climates, and require careful treatment with local antiseptics and either serums or vaccines.

Salivary calculi have been reported by Christopherson, and are certainly not uncommon in Europeans and natives, and are apt to recur after removal. A favourite seat appears to be the sublingual duct, where the calculus is apt, on superficial examination, to be mistaken for an enlarged lymph gland.

Espundia or oro-nasal leishmaniasis is fairly frequently met with, and is described on p. 2175; while *gangosa* or its syphilitic counterpart is frequently seen, and is described on pp. 1876-1879.

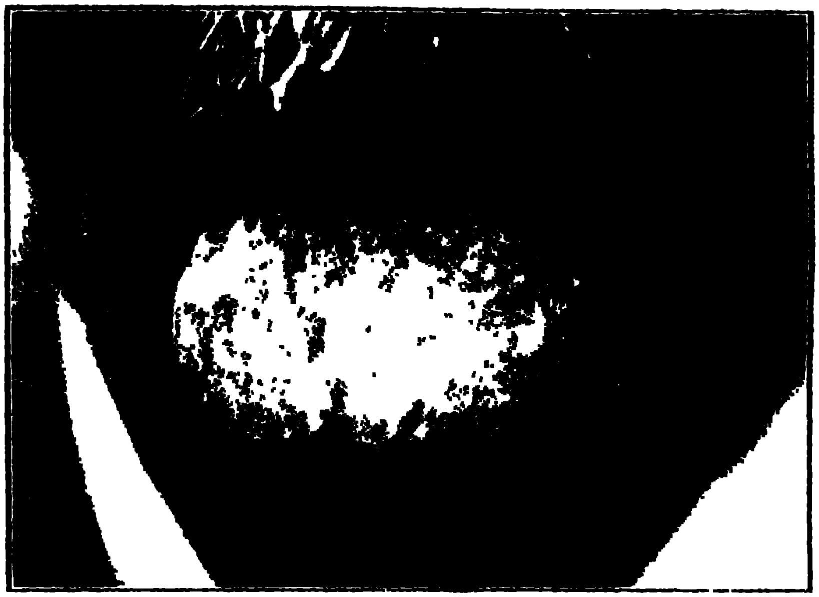

FIG. 742. LEUCOPLAKIA.

Leucoplakia and *cancers* of the lips, cheeks, and tongue are frequently met with in the tropics, and appear in a curious way to be related to mycetoma, via the condition called *paramycetoma* (*vide* Chapter XCIII., p. 2145).

THRUSH.

Synonyms.—Saccharomycetic stomatitis, Oral oidiomycosis. *French*, Muguet, Millet blanchet; *Italian*, Mughetto; *German*, Schwämchen.

Definition.—A stomatitis, or, more correctly, a group of stomatites, characterized by the presence of creamy white patches, believed in the past to be produced by *Oidium albicans* Robin, while at the present time it is recognized that they may be produced by a multiplicity of fungi.

Historical.—The affection was clinically known to Hippocrates, forming part of the στόματα ἀφθώδεα described by him. It was also certainly known to Galen under the term of *aphthæ albæ infantum*.

Sauvage called the affection *aphthæ lactamen*, and Bateman *aphthæ lactantium*.

In 1839 Langenbeck first discovered that the condition was due to a fungus. It is interesting to note that the thrush case, microscopically investigated by Langenbeck, was a patient suffering from typhoid, and that Langenbeck suggested that the fungus might be the cause of this malady.

Berg in Stockholm, in 1842, studied the condition very carefully and gave some details on the morphology of the fungus, while Vo demonstrated the contagiousness of the malady. Gruby, in 18. considered the fungus to belong to the genus Sporotrichum, an called the affection aphthaphyte.

Robin gave a full description of the fungus in 1847, and considered it to be closely related to *Oidium tuckeri*, which attacks the leaves of vine-trees, and to *Oidium lactis*. In 1853 he called it *Oidium albicans*.

In 1866 Hallier considered the fungus to be a Stemphylium, and called it *Stemphylium polymorphum*. In 1868 Quinquaud created a new genus, *Syringospora*, and named the fungus *Syringospora robini*. In 1877 Grawitz considered the organism to be identical with *Mycoderma vini*.

In 1878 Rees placed the fungus in the genus *Saccharomyces* (*S. albicans*). In 1885 Plaut grew it in pure culture and considered it to be identical with *Monilia candida* Bonorden, which is often found in cow-dung.

In more recent times the condition has been studied by Klemperer, Roux, Linossier, Vuillemin, and others, while Castellani has shown that the affection may be caused by a multiplicity of fungi. Pijper has recently described a case of thrush in South Africa due to *Hemispora rugosa* Castellani.

Climatology.—Thrush is very common throughout the tropics, but it is found also very frequently in temperate and cold climates.

Etiology.—It is generally stated that thrush is due to *Oidium albicans* Robin (synonyms: *Monilia*, *Saccharomyces*, *Parasaccharomyces*, *Endomyces*, *Syringospora albicans*, *Syringospora robini*, *Stemphylium polymorphum*), but the researches of Castellani carried out both in the tropics and in temperate zones have shown that the term *Oidium albicans* has been used to cover a multiplicity of fungi, and that the affection may be caused by hyphomycetes belonging to different species, genera, and families. The fungi capable of producing thrush may be classified as follows:—

Fungi Imperfecti :—
  Genus *Monilia* Persoon.
  Genus *Oidium* Link.
  Genus *Hemispora* Vuillemin.
Ascomycetaceæ :—
  Genus *Endomyces* Link.

Fungi of Genus Monilia Persoon.—Fungi of the genus *Monilia* Persoon are by far the most frequently met with, and there is little doubt that the fungus described by Robin under the name *Oidium albicans* belongs to this genus. For details on fungi of this genus the reader is referred to Chapter XXXIX., p. 1079. The species most commonly found in the tropics are of the types *Monilia tropicalis* Castellani, *Monilia pinoyi* Castellani, *Monilia parapinoyi* Castellani, less frequently of the *Monilia bronchialis* Castellani type and other types, while *Monilia albicans* Robin *sensû stricto* is seldom found.

In cases of thrush in London Castellani isolated in 1913 fungi of the types *Monilia pinoyi* Castellani, *M. parapinoyi* Castellani, *M. londinensis* Castellani, *M. metalondinensis* Castellani, *M. bronchialis* Castellani, occasionally *M. tropicalis* Castellani, and rarely other types.

Fungi of Genus Oidium Link.—The following fungi of the genus Odium have been found in a few cases of thrush:—*Oidium matalense* Castellani, *Oidium rotundatum* Castellani, *Oidium asteroides* Castellani. The same species have been found in the expectoration of certain cases of bronchitis, and *Oidium rotundatum* and *Oidium asteroides* also in the fæces of certain cases of enteritis.

Fungi of the Genus Hemispora Vuillemin.—The fungus *Hemispora rugosa* Castellani, found by Castellani in certain cases of subacute tonsillitis and cases of bronchomycosis, has been recently observed by Pijper in a peculiar case of thrush in South Africa.

Fungi of Genus Endomyces Link.—Vuillemin in old cultures of so-called *Oidium albicans* Robin found asci, and, therefore, considered the thrush fungus to be an endomyces. Vuillemin's findings were not confirmed, and Landrieux created a new species for the fungus in which Vuillemin found asci: *Endomyces vuillemini* Landrieux.

Predisposing Causes.—General weakness, marasma, and the late stages of tuberculosis and diabetes, favour the development of thrush, though at times perfectly sound individuals may suffer from it.

Symptomatology.—On the mucous membrane of the cheeks, soft palate, and tongue, white small spots appear, which gradually spread. There is often a certain degree of inflammation, and the oral mucosa may be red and swollen and the saliva very acid. Nursing and chewing are painful, and infants and children with thrush have often diarrhœa. Certain authors, however, maintain that the severe signs of stomatitis are not due to the thrush fungi; bacteria and other organisms would be the real cause of the oral inflammation, which would prepare the ground for the fungus to thrive, and by abundantly growing produce the white patches. Thrush not rarely spreads to the pharynx and the upper portion of the œsophagus. It is interesting to note that the fungus grows from the surface downward fairly deep into the mucous membrane. It was believed at one time that thrush never affected cylindrical epithelium. Thrush runs a variable course, and in many cases shows little tendency to spontaneous cure.

Clinical Varieties.—In cases of thrush due to *Oidium rotundatum*, *Oidium asteroides*, and *Monilia zeylanica*, the colour of the patches may be yellowish instead of creamy white. The same appearance has been recently noted by Pijper in an interesting case of thrush he has carefully described in South Africa, due to *Hemispora rugosa* Castellani.

Diagnosis.—The diagnosis can often be made clinically, the creamy white patches being characteristic, but it should always be confirmed by the microscopical examination, which will reveal a large amount of mycelial threads and conidial forms. If it is desired to know the ætiological variety of thrush the patient is suffering from, cultural methods are necessary. These are described in the chapter on Bronchomycosis (see p. 1888).

Prognosis.—Thrush *per se* is not a serious affection, but its occurrence in cachectic patients is a bad omen.

Treatment.—Glycerine of borax applied to the patches several times a day is efficacious in many cases, or an aqueous solution of borax (1 in 30) may be used. The addition of honey to the latter is to be deprecated. In resistant cases the addition of carbolic acid to the glycerine of borax, 10 minims to the ounce, will be found useful. In marasmic children or adults suffering from some incurable disease any treatment may fail to bring about a complete disappearance of the thrush.

Prophylaxis.—In the case of infants there is no doubt that in many cases the infection is carried by contaminated nursing bottles and their rubber nipples. These should, therefore, be kept scrupulously clean. As regards children, and more especially adults, quite a number of them, although in apparent perfect health, harbour thrush fungi in the mouth, and are, therefore, carriers. In them the use of alkaline tooth-pastes and mouth-washes is to be recommended.

GINGIVITIS.

During the last few years much attention has been paid to gingivitis, or inflammation of the gums, which may be divided into simple gingivitis, pyorrhœa alveolaris, and ulcerative gingivitis. They are all of tropical importance.

Simple Gingivitis.

In this disease the gums are bright red in colour, especially near the margin, becoming normal when traced towards the buccal mucosa. The interdental papillæ are swollen, but are neither painful nor ulcerated. There is no odour, no pain at night, and no enlargement of lymph glands, but the teeth may be covered with tartar and show food débris. A carbolic rose-water mouth-wash (½ per cent.) will be found useful.

Pyorrhœa Alveolaris.

This is a chronic condition, in which there is little sign of inflammation of the gums, but in which pus can by pressure be made to exude from the peridental pockets. If it is allowed to proceed unchecked it will produce ulceration of the bottom of the peridental sulcus and destruction of the periodontal membrane, and will set up a rarefying osteitis, which will injure the bony socket and loosen the teeth.

Ulcerative Gingivitis.

Synonym.—Mal de Bocha.

This was studied by Miller, an American dental surgeon, in 1882, who first saw the spirochætes and the fusiform organisms which were subsequently described by Vincent, in 1898, as the causal agent of a membrano-ulcerative pharyngitis and tonsillitis, a membrano-ulcerative stomatitis, and a membrano-ulcerative gingivitis, two of which are commonly present when a case comes to be noted, although the gingivitis is nearly always the primal disease.

All forms are common in the tropics, and their relative frequency has been investigated in Palestine by Schimeoni-Meckler, in 1917, who found that 78 cases of mouth disease could be resolved into 28 cases of ulcerative gingivitis, 17 of ulcerative stomatitis, 6 of Vincent's angina, and 27 of mixed types. The whole subject has been ably studied by Barlow in 1914, Bowman in 1916, by Taylor and McKinsty in 1917, and by Colyer, in 1918. There are three varieties of the complaint—viz., the acute, the subacute, and the chronic.

Acute Variety.—This is an acute inflammation of the margins of the gums, of gradual onset, but which spreads rapidly and causes ulceration of the interdental papillæ and sloughing of the gums around the necks of the teeth, and in severe cases ulceration of the oral mucosa, associated with malaise, fever, and enlargement of the lymph glands, hæmorrhage from the gums, and pain therein, especially at night, bad taste in the mouth, offensive breath, difficult and painful mastication, and loose and tender teeth. There is œdema of the interdental papillæ, which are bluish-red in colour or covered with a brownish friable slough. It usually attacks the gums around the upper incisor teeth, but may begin anywhere where food tends to accumulate. It spreads from person to person, but is commonly met with in persons living under bad conditions.

Subacute Variety.—The gums are spongy and tender, and a whitish pellicle often forms which on superficial examination may give the appearance of a purulent exudate. The condition often spreads to the cheeks and lips, and may involve the soft and hard palate and even the tonsils. The pellicle after a time separates, leaving an eroded surface which gradually deepens.

Chronic Variety.—If untreated the acute and subacute varieties pass into the chronic, and lead in a year or so to destruction of the bony sockets.

Treatment.—The best treatment for these infections is to remove the tartar, disinfect the mouth with a spray of peroxide of hydrogen or of glycothymoline, and then to treat by ionization with zinc sulphate, and afterwards to use antiseptic washes of sanitas or similar preparations. Roberts recommends the local application of the following: Hydrogen peroxide ʒv., vinum ipecac. ʒiii., glycerin ʒv., aq. ad ℥viii.

LINGUAL AFFECTIONS.

Patches of **Leucoplakia** of the tongue are common in natives, and may be of various origin—syphilitic, frambœtic, or due to irritation caused by smoking or chewing various substances. Case of the so-called **Circinate pityriasis linguæ** or **Annulus migrans** are not rare. **Lingua nigra** is occasionally seen. We have already called attention to the *dark patches* found on the tongue in natives, and which by some writers have been described as a sign of ankylostomiasis. These pigmented patches are roundish or oval, and may be found also on the gums, the mucosa of the lips, on the soft and hard palate, and are apparently congenital. A condition which might be called **Red or Purple tongue,** and which often puzzles the newly arrived medical man, who does not know its origin, is extremely common in Ceylon among the coolies and lower-class natives, and is simply due to chewing betel. The pigmentation slowly disappears on the native discontinuing the use of betel. Cases of **Furrowed tongue** (scrotal tongue) are not rare. We have seen a case of **Fordyce's disease** (pseudo-colloid of the lips) in a half caste. A case of **Chelitis exfoliativa** in a European lady and cases of **Perlèche** have been observed by us among European children. Under the term *seasonal recurrent ulceration of the lips*, Gros has described a very superficial ulceration on the lower lips in Algerian natives which is very common in the hot season, and is due, according to him, to a diplobacillus.

Pityriasis Linguæ Spirochætica.—This condition has been described by Castellani. There is as a rule no sign of acute inflammation and no ulcers, but the dorsum of the tongue is covered by a thick, persistent, whitish-yellowish or greyish-brownish fur, which on microscopical examination seems to consist solely of innumerable spirochaetes, with some epithelial cells. Of course, a few spirochætes are always found in scrapings from the tongue, but never in such enormous amounts.

HALZOUN.

Definition. Halzoun is the invasion of the pharynx by the adults of *Fasciola hepatica* (Linnæus, 1758), which cause dyspnœa, dysphagia, and sometimes more severe symptoms, and even death.

Historical. In 1904 Khouri described this disease as occurring in Northern Lebanon.

Ætiology.—The disease is caused by eating raw livers, especially raw goat (*Capra hircus* Linnæus) livers, which are infected with *Fasciola hepatica* (Linnæus, 1758), when the worm (p. 565) fastens itself on to the mucosa of the pharynx and sucks blood.

Symptomatology.—The patients suffer from dyspnœa, dysphagia, dysphonia, and congestion of the head, and occasionally die, but more usually, after lasting from a few hours to a few days, the victim vomits and the parasites are expelled, and recovery results.

Treatment.—An emetic will cause the parasites to come away.

TONSILLAR AFFECTIONS.

Every type of tonsillitis met with in temperate climates is observed also in the tropics, although there is no doubt that tonsillar and throat affections are less frequent in warm climates than in cold. Diphtheria is on the whole less frequent than in temperate zones, but a fairly large number of cases occur in every tropical country. We have seen a number of cases of **follicular tonsillitis** and other streptococcal affections; **quinsy** or tonsillar abscess is not rare, and cases of **Vincent's angina** occur, due to Vincent's *Bacillus fusiformis* in association very often with spirochætes. We do not propose giving a description of Vincent's angina, which may be found in any text-book on general medicine, but we would call attention to the possibility of mistaking it for a syphilitic condition. Certain authorities state that Wassermann reaction is positive in Vincent's angina, but in our experience this is not so, and we can confirm the researches of Taylor and others, according to which Wassermann reaction is negative in Vincent's angina, except, of course, when it develops in a syphilitic person. Cases of tonsillitis possibly due to amœbæ and flagellates have also been recorded. We propose saying a few words on certain affections of the tonsils to which little attention has so far been paid—viz., mycotic infections.

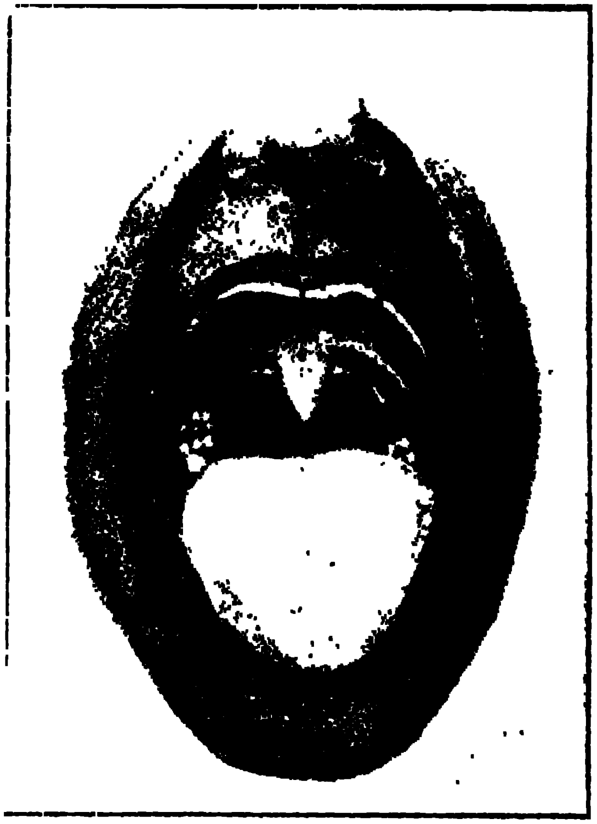

FIG. 743.—TONSILLAR AFFECTION CAUSED BY *Hemispora rugosa* CASTELLANI.

Tonsillar nocardiomycosis and lesions of the tonsils due to *Nocardia bovis* and other species of the genus Nocardia and Cohnistreptothrix have been placed on record, but we desire to call attention to the comparative frequency of a granular Nocardiasis of the crypts which may lead to the formation of tonsillar calculi. The affection, which is not new, but is little known, runs a chronic course and is not painful. The patient often does not come to consult the doctor because of sore throat, but because of the unpleasant odour of the breath. On examination the teeth and gums may be quite healthy, but on examining the throat small whitish-yellowish spots will be seen on the tonsils; these spots are in reality the surface portion of granules contained in the crypts, and may be extracted with more or less ease. These bodies when squashed have a very offensive odour; under the microscope they consist of masses of Nocardia-like organisms at times, at other times masses of leptothrix; in certain cases both Nocardial fungi and Leptothrix are seen and various bacteria, and even protozoa such as amœbæ and flagellates The nocardia fungi are very difficult to grow. After several years the masses in the crypts may become calcified, and real calculi may be formed, which at times are the starting-point of some very severe inflammation.

Varieties of Tonsillonocardiasis.— Clinically the usual form is the yellow or whitish type. A case observed by one of us was characterized, however, by the presence of black granules, from which a nocardia similar or identical to *Nocardia nigra* Castellani, 1912, was grown.

Tonsillar moniliomycosis.- Moniliasis of the tonsils has been described by Castellani. Three types may be distinguished: the acute, the subacute, the chronic. The *acute type* is important, as such cases have often been taken for diphtheria. The tonsils are covered by creamy white patches, which at times extend to the soft palate, the pharynx, and larynx. There is difficulty in swallowing, and the patient may have some fever. Diphtheria is often suspected, but the microscopical and cultural examination clears the diagnosis at once. The fungus most commonly found in Ceylon is *Monilia tropicalis* Castellani. Cases of mixed infections of diphtheria and moniliasis have occasionally been seen by us.

In the *subacute* and *chronic* types of moniliasis the subjective symptoms are often nil. The diagnosis is based on the microscopical examination. The treatment consists in applications of glycerine of borax and of carbolic acid.

Tonsillar Oidiomycosis.- The condition is due to fungi of the genus *Oidium* Link. Clinically the affection is very similar to moniliasis, but in the case in which *Oidium rotundatum* Castellani was found the patches were yellowish and not white.

Tonsillar Hemisporomycosis.- In certain cases of tonsillitis in Ceylon Castellani found a fungus which he had previously observed in cases of bronchomycosis. He was doubtful about the classification of the fungus, and at first placed it temporarily in the genus Monilia, naming it *Monilia rugosa* Castellani, 1909. Recently Pinoy has placed it in the genus Hemispora, the name of the fungus becoming *Hemispora rugosa*.

The case in which the fungus was first observed had been suspected by the house physician to be a case of diphtheria, as the patient complained of great pain in swallowing. There was fever, the submaxillary lymphatic glands were enlarged, and on examination of the throat several greyish patches were seen on the left tonsil and on the soft palate. At times, however, the patches are yellowish. Under appropriate treatment they become smaller and smaller, but one or two small spots remain often for weeks and even months. As regards treatment, painting with a 5 or 10 per cent. solution of carbolic acid is found useful.

GASTRIC DISEASES.

All forms of **Dyspepsia** are common, but hyperchlorhydria and fermentation are especially common in our experience.

Ulcers and **Cancers** of the stomach are met with at times, as well as dilatation of the veins at the lower end of the œsophagus, leading to severe hæmatemesis. In children **Pyloric stenosis** has been seen several times by us. We have met with one case of diffuse inflammation which resembled 'phlegmon of the stomach' in its gastric symptoms, but which was associated with other signs pointing to a more general poisoning of the system.

EARTH-EATING.

Synonyms.—Geophagy. *French:* Mal d'estomac.

Remarks.—Earth-eating is common in many parts of the tropics, especially in certain parts of Africa (*e g.*, the Sudan and Southern Tunisia) and Asia (Malasia, Java, Borneo), but is observed also in Temperate Zones, in Europe, Northern China, and Japan. It is common in children and pregnant women. It is believed to be acquired by the children being left to crawl about and eat anything which comes to hand. It is also acquired by being taken as a remedy for syphilis and other diseases.

Christopherson says that it is common in the Sudan, where two forms of earth are eaten: (1) Karkooti (Nile mud), (2) taffel (some form of calcium carbonate). In Giava the earth eaten consists of bituminous clay, called 'ampor,' which is taken especially by pregnant women, who believe it will benefit their unborn babies. In Guatemala and other Central American countries natives occasionally eat a yellowish earth containing sulphur as a prophylactic against disease. In Japan it is said that the Ainus used to eat a paste made of starch and of diatomaceous earths in famine years.

Symptomatology.—The symptoms are usually emaciation and anæmia, with pain in the epigastrium and a sensation of hunger, while constipation is common. Earth-eaters frequently suffer from ankylostomiasis, and often have a yellowish muddy or earthy colour.

BELYANDO SPEW.

Synonyms.—Grass sickness (Western Australia). Gastric spirochætosis (Ernest Black).

Definition.—A gastric disturbance characterized by vomiting; occurring suddenly after meals, and unaccompanied by nausea in certain tropical regions without any immediate cause.

History.—Under the above terminology Dr. Ernest Black has described to us a disease which he has met with in Western Australia.

Geographical Distribution.—It has long been known as a distinct disease in Queensland under the name derived from the Belyando district, 250 miles inland, and in Western Australia in certain tropical districts, chiefly coastal, where it is called 'grass sickness.' It also exists in some tropical districts in Brazil.

Ætiology.—The cause of the disease is unknown. Black has found a spirochæte in the mucous membrane of the stomach. This spirochæte is of variable size, small and slender.

Black thinks that, like other members of that class, it generates no free toxins, but its pathological effect is produced, on its death and disintegration, by the liberation and absorption of toxins.

The mode of conveyance is not conclusively determined, but it seems to be by means of contaminated food or water. In one district in Western Australia all the evidence pointed to milk as the medium. In Queensland, on the other hand, many years ago there was no fresh milk used in a district where the disease was common.

Climatology and Incidence. In Queensland it persisted in the past in an endemic area in spite of a drought lasting several years. In Western Australia the outbreaks are strictly limited to the wet season, and start with the rapid growth of grass after the first rains. Hence its local name in that district.

Persons of both sexes, any age, and all races may be affected, those in robust health equally with those in ill health.

Symptomatology. The solitary symptom is vomiting, which occurs only after taking food. This may be within a few minutes, or may be delayed for some time after a meal. The character of the vomiting is quite distinctive, and reminds one of the action of apomorphia. It is very sudden, and rarely preceded, accompanied, or followed by any nausea, straining, or pain. There is seldom any premonitory sensation, consequently it is so sudden as often to be extremely embarrassing. It may occur after every meal or only after one or two meals in a day. It may be every day, or there may be intervals of one or several days between the attacks, which also vary in their duration. From the results of experiments, Black has come to the conclusion that the attacks are concurrent with and due to the death of some of the organisms, and that the intermissions are periods during which none or too few die. In the intermittent form there is little if any interference with the general health, but in the more or less continuous cases there is sometimes considerable loss of weight, the malnutrition then resulting in ill health. There is no loss of appetite, but rather the reverse. If the attacks are short and the intermissions long, patients, especially children, sometimes increase in weight.

Treatment. According to Black, the aim of the treatment is to destroy the causal organism in the mucous membrane of the stomach. Cyllin in palatinoids of 3 minims each with a wineglassful of water three times a day is generally effectual and convenient. Thymol may be given in 1 grain doses three times a day, the patient being warned not to take any alcohol or oil. Chlorine solution, freshly prepared, has been strongly recommended. Other drugs suggested are carbolic acid, creosote, and β-naphthol. Whatever drug is used, it should be given at least half an hour before meals.

Prophylaxis. Nothing is known about this.

ENTALAÇÀO.

Synonyms. – Mal d'engasgo, Dysphagie Tropicale, Tropical Cardiospasm.

Remarks. This disease has been known for a long time in certain parts of Brazil, having been described by Botelo, Langard, and by Paranhos. Bouchard has noticed a somewhat similar disease in pheasants which is due to a worm.

Climatology. –It appears to be localized to some districts in the interior of Brazil.

Ætiology. – The causation is unknown, but it has been suggested that it is a parasitic disease, that it is a neurosis, or that it is connected with eating diseased manioc. The last theory has been brought forward by Paranhos.

Morbid Anatomy. –No macroscopical lesions have so far been discovered.

Symptomatology. –The patient complains of severe difficulty in swallowing even liquids, and feels as though the food had stopped in the œsophagus and had not reached the stomach; hence the name 'd'engasgo,' meaning choked. During the attack the patient becomes anxious-looking, throws the arms about, and becomes dyspnœic. The face is congested and the eyes protrude. The swallowed food is brought up by a process of regurgitation rather than of true vomiting. The attacks are recurrent, with intervals of freedom. After a time the patient may become cachectic from lack of nutrition, and die.

Treatment.—This is very unsatisfactory, and merely symptomatic. Bromides and chloral have been given, but a change of climate is essential.

CHAPTER LXXV

HELMINTH INFECTIONS

General remarks—The intestinal trematodiases—The intestinal cestodiases—The intestinal nematodiases—Trichuriasis—Ankylostomiasis—Ascariasis—Oxyuriasis—Intestinal polyparasitism—Rare infections—References.

General Remarks.

In the present chapter we propose to consider the helminth infections of the intestines and in so doing exclude those found in the liver or the bloodvessels of the intestines, though it is true that the eggs in both cases may be found in the fæces.

The Intestinal Trematodiases.

Definition.—An intestinal trematodiasis is an infection of the alimentary canal with adult trematode worms.

Remarks.—The intestinal trematode worms of man are:—

1. *Watsonius watsoni* (Conyngham, 1904).
2. *Gastrodiscus hominis* (Lewis and McConnell, 1876).
3. *Fasciolopsis fülleborni* Rodenwalt, 1909.
4. { *Fasciolopsis rathouisi* Poirier, 1887.
   { *Fasciolopsis buski* Lankester, 1857.
5. *Heterophyes heterophyes* (von Siebold, 1852).
6. *Metagonimus yokogawai* (Katsurada, 1913).
7. *Echinostoma ilocanum* Garrison, 1908.
8. (?) { *Echinostoma* (*Euparyphium*) *malayanum* Leiper, 1911.
   { *Artyfechinostomum sufrartyfex* Clayton Lane, 1915.

Eurytrema pancreaticum (Janson), fully described by Loos (*Annals of Trop. Medicine*, 1907, vol. i., p. 128), has occasionally been found in man in China.

In addition to adult worms, the ova of the Schistosomidæ (Chapters XXIV., LXIV., LXXVII., and LXXXIII.) and those of the liver flukes (Chapter LXXXI.) pass down the alimentary canal and escape in the fæces.

Fasciola hepatica is the cause of halzoun, described in Chapter LXXIV., p. 1746.

Symptomatology.—Diarrhœa has been described as being caused by ***Watsonius watsoni*** (p. 562), while ***Fasciolopsis buski*** (p. 568) causes dysenteric diarrhœa, ***F. rathouisi*** (p. 568) colic, ***F. fülleborni*** (p. 569) fever, and ***Kwan's fluke*** (p. 569) gastric disturbance, but the recorded cases are few, the method of infection is unknown, and the symptomatology has still to be carefully studied.

Diagnosis.—The presence of trematode worms can only be diagnosed by the discovery of the eggs or the adult in the fæces.

Treatment.—The treatment must be on the same lines as that described for ankylostomiasis.

Intestinal Tæniiases.

Definition.—An intestinal tæniiasis is an infection of the alimentary canal by adult cestode worms.

Symptomatology.—*Cestode parasites* cause gastric and reflex symptoms, mostly of a vague nature. The former comprise salivation, diarrhœa, or constipation, with colicky pains, nausea, vomiting, or dyspepsia, while the latter include faintness, unequal pupils, disorders of vision and hearing, headache, itching of the nose or anus, vertigo, epilepsy, etc. Anæmia and skin eruptions have also been recorded. Christopherson and Izzedin have recorded a case of acute intestinal obstruction due to *Tænia saginata*.

Treatment.—The treatment is the usual anthelmintic remedy of *Filix mas*, in capsules (six 10-minim capsules) or emulsion—such as olei filicis ʒi. to ʒi.ss., gummæ acaciæ q.s., syrupi zingiberis ʒi., aquæ ad ℥ii. Fiat haust. To a child six to eight years of age olei filicis ʒss. may be administered, followed by a saline purgative six hours later. Filmaron, which contains the active principle of filix, may be given in capsules (two or three). Turpentine may be given in doses of 20 minims three times a day, or kousso 2 drachms, or kamala 1 drachm. Thymol has also been recommended. Naphthalene in 2-grain doses has been used in children.

Tæniasis is extremely common in certain parts of the tropics—as, for instance, Abyssinia—where some natives take every two months kousso flowers (*Brayera anthelmintica* Kunth). Several other native drugs have been used, among which, according to Annaratone, the following are the principal ones: Bulbs of *cossala* (Mollugoliro), *habbeciacco* (seeds of *Oxalis anthelmintica*), the bark of

OVA OF INTESTINAL WORMS AS SEEN IN THE FÆCES.

TREMATODA

F, Schistosoma japonicum (after Leiper).
P, Schistosoma mansoni (after Holcomb).
G, Fasciolopsis buski (after Looss).
H, Heterophyes heterophyes (after Looss).
Q, Dicrocœlium lanceatum (after Looss).

CESTODA

J, Dibothriocephalus cordatus. (Outline only to show relative size. Figure K is placed inside it in order to economize space.)
L, Tænia solium (after Leuckart).
M, Tænia confusa (modified after Guyer).
N, Dibothriocephalus latus (modified after Schauinsland).
O, Tænia saginata (after Leuckart).
R, Hymenolepis nana (after Stiles).
T, Hymenolepis lanceolata (after Railliet).
W, Hymenolepis diminuta (after Blanchard).
S, Dipylidium caninum (after Diamare).
V, Diplogonoporus grandis (after Brumpt).

NEMATODA

A, Ancylostoma duodenale.
B, Strongyloides stercoralis (after Thayer).
C, Oxyuris vermicularis (after Leuckart).
D, Necator americanus.
E, Trichostrongylus instabilis (after Ward).
I, Gigantorhynchus gigas (after Ward).
K, Trichuris trichiura. (Placed inside the outline of Dibothriocephalus cordatus for the sake of economy in space.)
U, Ascaris lumbricoides.
X, Ascaris, sp.? (We have seen large eggs of this nature in Ceylon.)

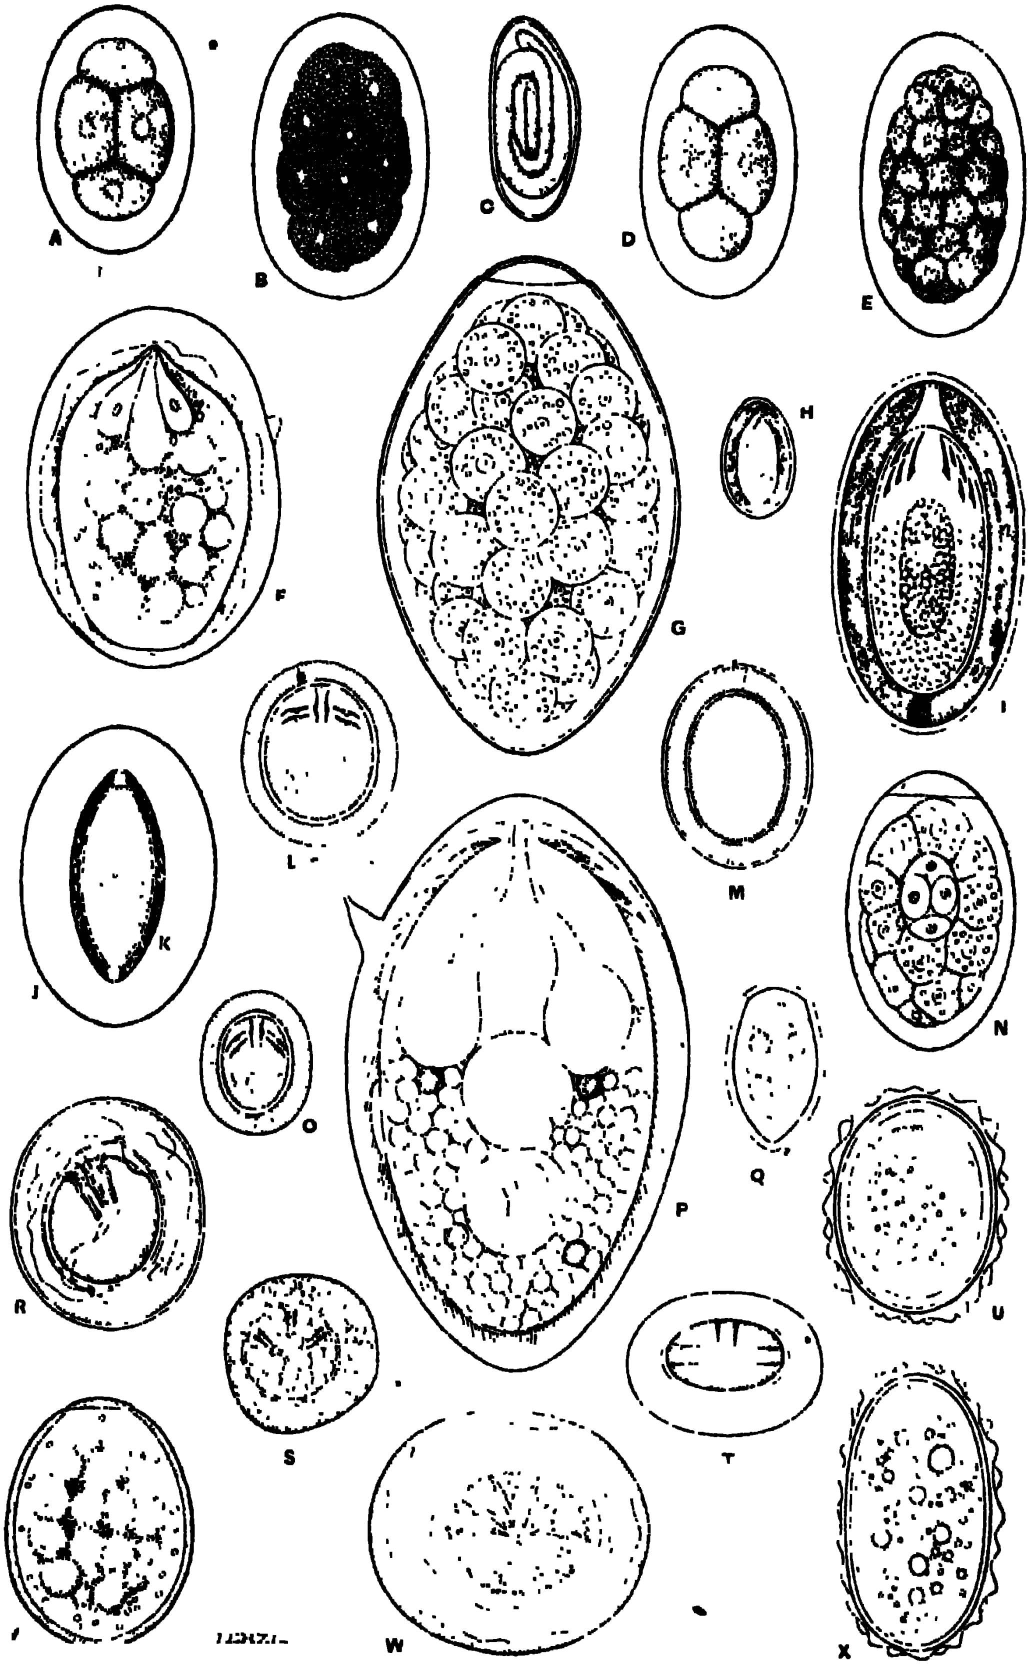

FIG. 746.—OVA OF INTESTINAL WORMS AS SEEN IN THE FÆCES.

Albizzia anthelmintica (Bessina), flowers and leaves of buddleia, polistachya (*mattari*), the bacchæ of *Mœsa lanceolata* (Saoria), and of *Nijrsine africana* (*ssa'hlso*), leaves, flowers, and fruits of *Celosia ervgina* (*bellilda*), efficacious also for ascarides. Large doses of melon seeds are also used.

(After Braun.)

Rare Tæniiases.

Some of the Tæniiases—*e.g.*, those due to *Tænia philippina*, *T. confusa*, *T. bremneri*, *T. hominis*, and *T. africana*—are so rare that no further mention is necessary beyond the descriptions which have been given in Chapter XXV., p. 614.

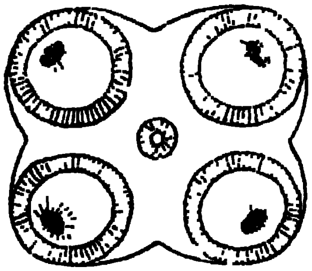

FIG. 749.—*Tænia africana*.
(After von Linstow.)

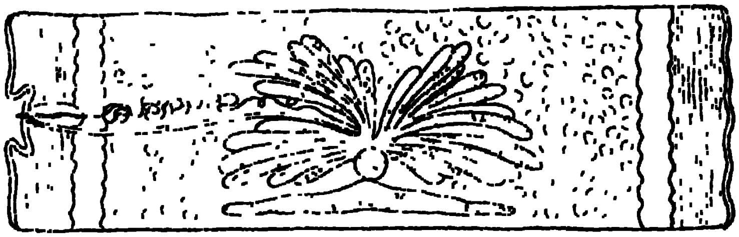

FIG. 750.—*Tænia africana*.
(After von Linstow.)

The Dibothriocephaliases.

The Dibothriocephaliases are produced by *Dibothriocephalus latus*, *D. cordatus*, and *D. parvus*. *D. latus* (p. 604) causes severe anæmia, and at times fever associated with serious symptoms, but this infection is not common in the tropics. The treatment is the same as for Tæniiasis.

The Diplogonoporoses.

Diplogonoporosis is found in Japan, where it is due to *Diplogonoporus grandis* (p. 605), and in Roumania, where it is caused by *D. brauni* (p. 605). The recorded symptoms somewhat resemble those produced by *Dibothriocephalus latus*.

Hymenolepsiasis.

Hymenolepsis nana (p. 610) may give rise to severe reflex nervous symptoms, but only when present in considerable numbers. It has been found in Egypt, Siam, Japan, North and South America, and Europe, and is by no means a rare parasite in man. *H. diminuta* (p. 609) is a common parasite in rats, but does not occur so frequently in man, though a number of cases have been recorded in America and Europe. It does not cause any appreciable symptoms.

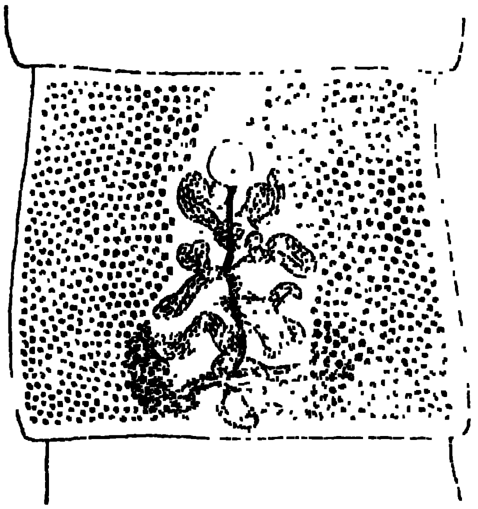

FIG. 751.—*Dibothriocephalus latus* (PROGLOTTIS).

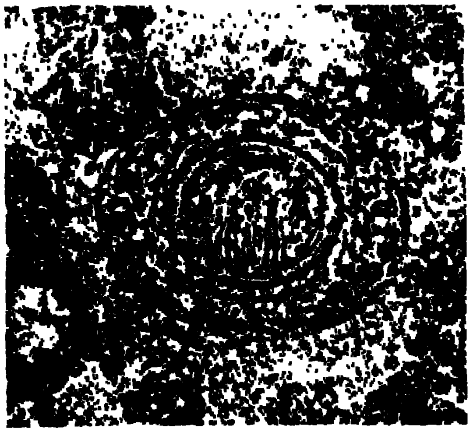

FIG. 752A.—EGG OF *Hymenolepsis nana* IN HUMAN FÆCES. (× 300)

Dipylidiasis.

Dipylidium caninum (p. 608) has often been found in man, but is harmless.

Davaineiasis.

Davainea madagascariensis (p. 611) is normally found in birds, but about nine cases have been recorded in children in Madagascar, Mauritius, Siam, and New Guinea.

Intestinal Nematodiases.

Definition.—Intestinal nematodiasis is the invasion of the alimentary canal by adult nematode worms.

Strongyloidosis.

Synonym. Intestinal anguillulosis.

Strongyloidosis, usually called intestinal anguillulosis, is the infection of man with *Strongyloides stercoralis* Bavay, 1876 (*vide* p. 628), which produces no symptoms if present in small numbers, but induces an intestinal catarrh leading to anaemia and an intermittent diarrhœa when in large numbers. The disease is met with all over the tropical world, and even in the temperate zone. Diagnosis can only be effected by finding the rhabditic embryo (the so-called *Anguillula stercoralis*) or the eggs in the fæces, in which the latter will only be found when violent diarrhœa is present. The treatment is the same as for ankylostomiasis.

Trichuriasis.

Synonyms. Whip-worm infection, Trichocephaliasis.

Nomenclature.—Büttner in 1761 first named the worm *Trichuris*, or thread-tail, for he mistook the posterior end for the anterior. Linnaeus in 1771 called the worm *Ascaris trichiura*, but Goeze in 1782 changed the name to *Trichocephalus trichiura*, because he recognized the error made by Büttner. The term *Trichuris trichiura* Linnaeus must, however, stand, and the term for any disease associated with this worm must be ‘trichuriasis’

Definition. Trichuriasis is an infection of the large intestine appendix, or ileum by *Trichuris trichiura* Linnaeus, 1771 (*vide* p. 677), which produces no symptoms unless it is present in large numbers, when anæmia, nervous and gastro-intestinal symptoms may appear.

History.—From the time of Barth, who, in 1845, was the first to ascribe a pathogenic rôle to the worm, there have been a large number of observers who have considered it to be the cause of gastro-intestinal and nervous symptoms, while Metchnikoff and Guiart in 1901 considered it to be a cause of appendicitis. In the same year Girard drew attention to the possible transmission of pathogenic bacteria into the tissues via the wounds produced by the worm. In 1902 Schiller ascribed a case of high fever to the action of a heavy infection with the parasite. In 1908 Musgrave, Clegg, and Polk contributed an excellent monograph on the whole subject of trichuriasis, together with full accounts of four cases. Our own experience is in favour of the worm being occasionally directly the cause of appendicitis, for several times we have found it in the inflamed appendix removed by operation.

Geographical Distribution.—*Trichuris trichiura* is cosmopolitan in its distribution.

Ætiology.—Trichuriasis is caused by *Trichuris trichiura* Linnæus, 1771, which, as far as is known, is really a parasite of man and monkeys, while allied forms exist in other animals. The eggs escape with the fæces, and require three to six months for the development of the embryo, which can then remain alive for years inside the shell if kept on moist earth. Usually the eggs gain access to man by means of contaminated food, especially uncooked vegetables, and to a less extent fruits This is especially likely to occur in the tropics, where human fæcal matter is often allowed to be deposited in vegetable gardens. Musgrave, Clegg, and Polk report finding the ova in washings from fresh vegetables. Domestic animals, insects, flies, dust, etc., are also considered to be possible means of infection. When taken into the alimentary canal, it hatches and reaches sexual maturity in sixteen days.

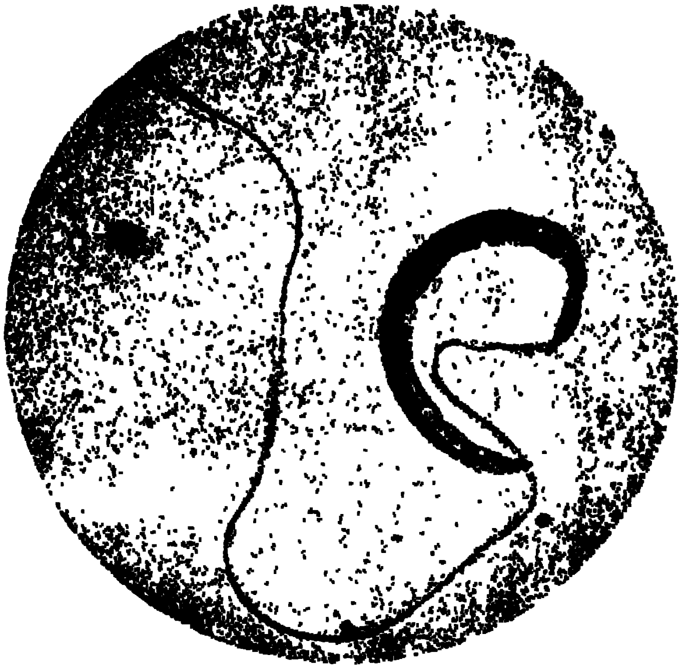

FIG. 753 *Trichuris trichiura.*
(Microphotograph by J. J Bell)

It occurs more commonly among children than adults, women than men, and native races than European. But all these factors appear simply to depend upon good or bad sanitation, for the latter is the principal factor in producing infection.

Pathology. It is believed that the worms attached themselves to the mucosa of the bowel by the head penetrating deeply into its tissue either via a gland or directly. In this position the worm is firmly fixed, and is more or less protected against the action of anthelmintics. They do not appear to be blood-suckers, nor is there any evidence that they produce toxins—at all events, in sufficient quantity to affect man. On the other hand, it is believed that micro-organisms can gain entrance to the blood through the wounds produced by the head, and this secondary infection may be the cause of the appendicitis and other pathological phenomena.

Morbid Anatomy.—A post-mortem simply reveals anæmia and dropsy, with at times appendicitis. The most marked feature is the presence of large numbers of *Trichuris trichiura*.

Symptomatology.—The symptomatology may be subdivided into the intestinal and appendicular varieties.

Intestinal Variety. The illness begins with dizziness, tinnitus aurium, and a sensation of weakness, which may be followed by slight daily fever and later by œdema of the face and extremities, while anæmia appears and gradually progresses. Seen at this stage of the illness, the mucosa of the lips and tongue appear pale, the appetite is poor, and dyspepsia, followed later by nausea and vomiting, with or without slight diarrhœa, occurs.

The liver and spleen are normal, but a hæmic murmur may be heard at the apex of the heart, while the blood examination reveals a great decrease in the number of red cells and the presence of poikilocytes, but as a rule no nucleated elements. The hæmoglobin is also reduced, while the leucocytes are increased, and also in most cases there is an absence of an eosinophilia. The urine is normal. There is mental depression, restlessness, headache, and at times insomnia. As the disease progresses the anæmia becomes more and more marked, and death may eventually ensue.

Appendicular Variety. The symptoms of this variety are the same as those for appendicitis arising from other causes. Operative treatment reveals the nature of the malady. The symptoms are the same as those for appendicitis due to other causes—viz., severe pain in the region of the appendix, tenderness on pressure, with often vomiting and fever.

Diagnosis.—The disease closely resembles ankylostomiasis, from which it may be differentiated by finding trichuris ova and no ancylostome ova in the fæces, and also by the absence of marked eosinophilia.

Prognosis.—The ordinary slight infection which is frequently met with may be considered to be harmless, but the prognosis is grave in those rare cases of very heavy infection presenting the symptoms described above.

Treatment.—The treatment at present advised is the administration of thymol by the mouth in the manner presently to be described for ankylostomiasis, and enemata of solutions of benzine.

Prophylaxis.—Good sanitation and proper disposal of sewage, associated with cleanliness in the preparation of food, as well as with personal cleanliness, constitute important prophylactic measures. Uncooked vegetables and skins of fruits should not be eaten.

Ankylostomiasis.

Synonyms.—Ancylostomiasis (this is the latinized Agchylostomiasis, and is a term much recommended by many authorities), Agchylostomiasis, Anchylostomiasis, Uncinariasis, Dochmiosis, Dochmiasis. *Latin*: Anemia intertropicalis, Hypoæmia intertropicalis, Geophagia (*pro parte*). *English*: Ceylon anæmia, Negro consumption, Tropical chlorosis, Egyptian chlorosis, Miners' anæmia, The Great-lazies (Florida), Tunnel-workers' anæmia, Hook-worm disease, Porto Rican anæmia. *French*: Anémie des Pays Chauds, Cachexie Africaine, Mal de Cœur, Mal d'estomac, Ankylostomasie. *Italian*: Anchilostomanemia, Anchylostomiasi. *German*: Ankylostomen-Krankheit, Tunnelkrankheit, Wurmkrankheit. *Spanish*: Aquilostomiasis. *Portuguese*: Oppilação, Amerellao, Cançação. *Arabic*: Ribâgan, Sulura, Tun-tun.

Definition.—Ankylostomiasis is a toxæmia resulting in a progressive anæmia, caused by *Ancylostoma duodenale* Dubini, 1843, and *Necator americanus* Stiles, 1902.

History.—The history of the discovery, together with the structure, life-history, and geographical distribution of the two parasites, has been described on pp. 666-673, and it now remains to give an account of the history of the disease produced by them in man.

If the references contained in the Ebers papyrus, as well as those in the 'Harita Samhita,' really refer to ankylostomiasis, they would make the history of the knowledge of the disease very ancient. It was, however, early recognized that there was a fatal disease of unknown causation in the New World. Thus in 1648 Piso, in his work 'Historia Medica Brasiliae,' gives an account of a fatal disease, Oppilatio (or Oppilação), present in Brazil, by which he probably meant ankylostomiasis. After him it was described by Père Labat in Guadeloupe in 1742, by Chevalier in St. Dominique in 1752, by Desportes in the same place in 1770, by Bayon in Cayenne in 1780, by Hunter in Jamaica and Rodschield in British Guiana in 1796, by Bryon Edwards in Jamaica in 1799, by Pitt in 1808 in the United States, and by Moreau de Jonnès in 1816 in Guadeloupe, while Chabert's celebrated account appeared in 1821. In Peru Castelnau found it in 1820, Jobim in Brazil in 1835, and Clarke in West Africa in 1860. In the meanwhile a peculiar anæmia had been found among miners, first of all in Hungary in 1786, and later in France, Belgium, Germany, and Cornwall, which for a long time was misunderstood, until Dubini's worms were found in the victims. In fact, nothing certain could be said about this peculiar form of 'tropical anæmia' or 'miners' anæmia' until Dubini found *Ancylostoma duodenale* as the cause of the disease, thus definitely separating ankylostomiasis from 'malarial cachexia,' and also clearing the diagnosis of miners' anæmia and tunnel disease. He proposed the name *Agchylostoma* for his new worm, deriving it from ἀγκύλος, meaning 'bent,' and στόμα, meaning 'mouth,' which he latinized into *Agchylostoma*, which therefore ought to have remained as the name of the worm, though *Ancylostoma* is doubtless a better rendering. Still, whether he misspelt the word or not, his name, according to the old rules of nomenclature, ought to have stood, but the Zoological Committee decided otherwise, and we have no choice in the matter, and simply carry out the rules for the time being in force. After his discovery the recognition of the disease spread, at first slowly, but later rapidly. Thus Bilharz in 1853 and Griesinger in 1854 recognized it in Egypt, and Wucherer in 1872 in Brazil, while Grassi and Parona, in 1877, drew attention to the importance of finding the ova in the fæces as a method of diagnosis, and in 1899 Ashford drew attention to the importance of the high eosinophilia. In 1898 Looss traced the method of infection by the skin, the lungs, trachea, etc., while more recently Sambon, Fülleborn, and v. Schilling-Torgau have traced a subsidiary route from the lungs via the blood-stream to the alimentary canal. In 1902 Stiles described *Necator americanus*, and in the same year Boycott and Haldane found the disease in the mines of Cornwall.

Climatology.—The disease will be found wherever there is a suitable temperature and moisture for the development of the parasites. It is therefore spread throughout the tropics of America, Africa, and Asia, and is also found in Queensland, New Guinea, and Fiji, and also in mines or tunnels in Europe, where the conditions of temperature and moisture resemble the tropics.

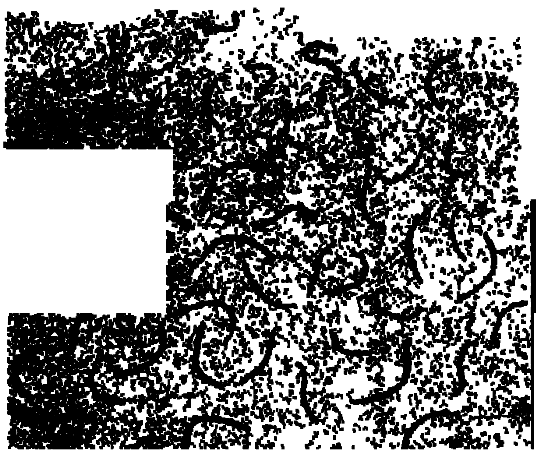

FIG 754.—*Necator americanus.* (Natural size.)

Ætiology.—The disease is due to the presence of *Ancylostoma duodenale* and *Necator americanus* in the body. These parasites, as far as is known, live entirely in human beings, and are therefore kept alive by '*patients*' suffering from the disease and by '*carriers*' or persons infected with so few worms that little or no symptoms are produced. As already noted, the larvæ live in earth, and infection takes place by two routes either through the skin or by the mouth. In the latter instance, it is generally acquired by eating contaminated vegetables, or through the habit of geophagy met with in some natives. It is probable, in our opinion, that the pathological phenomena may, partly or principally, be due to toxins, either set free by the embryo in its travels from the skin to the alimentary canal, or inoculated into the blood-stream from the cephalic glands of the adult worm as it grips the villi of the intestine. But absolute proof is still required of the presence of these toxins, notwithstanding the work of De Giovanni, Loeb, Gabbi, Noc, Alessandrini, and many others. Weinberg's researches on various helmintotoxins must be specially mentioned. The Porto Rico

Commission confirms the suspicion which had long existed as to a relative racial immunity, finding 71 per cent. of the cases in Europeans, 54 per cent. of the cases in mulattoes, and 41 per cent. of the cases in negroes, to vary from medium to very severe, though the degree of infection of the three races was in the proportions of 78 per cent., 72 per cent., and 76 per cent.

With regard to the two worms it is useful to note that *Ancylostoma duodenale* is larger and coarser looking, with thicker and coarser head, armed with four hooks on the buccal rim, and with the dorsal conical tooth not markedly projecting into the mouth. Female with sexual opening in the posterior third. Male with larger caudal bursa, with dorsal lobe. Ova slightly smaller. *Necator americanus* is smaller, with small and finely tapering head, simple chitinous lips on the buccal rim, dorsal conical tooth projecting well into the mouth. Female with sexual opening in the anterior half of the body. Male with smaller bursa and subdivided dorsal lobe. Ova slightly larger.

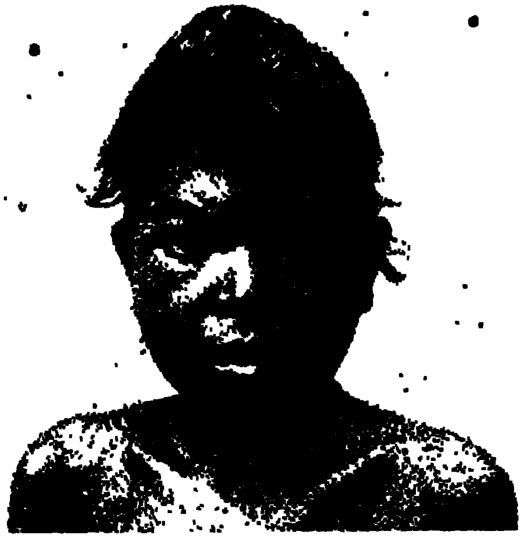

FIG. 755.—CASE OF ANKYLOSTOMIASIS.
(Note the swollen face.)

Pathology.—When the embryos enter the skin in sufficient numbers they cause an eruption of papules or vesicles, but some of these are more probably due to the pyococci and bacteria introduced along with the larvæ, which are the true cause of the dermatitis, as alcoholic extracts of the larvæ are said to produce similar lesions. These skin lesions are called 'bunches' in Cornwall, 'mazamorra' in Porto Rico, and 'ground-itch' in Assam. Smith has shown that experimental dermal infection with *N. americanus* causes local itching and a macular eruption, followed next day by a vesicular rash and swelling of the part, and on the fifth day marked swelling and enlargement of the lymph glands. This dermatitis disappears by the twelfth day. There may be sore throat and uneasy sensations in the stomach for a few weeks, and the ova appear in the fæces about the middle of the seventh week.

It is not known what effect the journey from the skin to the alimentary canal has upon the host, but it is certain that in course of time a marked effect upon the blood and the organs of the body is produced, which often appears out of proportion to the number of worms which can be found in the intestine. Loeb and Smith find that the worm produces a substance which hinders the coagulation of the blood. Some observers—*e.g.*, Gabbi—have found that the blood of ancylostome patients is more toxic than the blood of healthy people, and contains more hæmolytic substances, but this has been denied by Marini. Padoa and others have observed that the processes of intestinal putrefaction are very marked in ankylostomiasis. In our opinion the anæmia is due to a complex of causes—viz., the hæmolytic toxins secreted by the worm, actual loss of blood from the bites of the worms, and microbic secondary infections.

Morbid Anatomy.—An eruption about the feet, œdema about the ankles, with a peculiar dead-white appearance of the conjunctiva, are often seen on the post-mortem table. On opening the abdomen, it will be noted that the tissues are damp, the peritoneum sodden, the intestines very pale, and some straw-coloured fluid will generally be seen in the peritoneal cavity. All the organs appear damp and pale. The lungs are œdematous, the heart pale and fatty, with sometimes hypertrophy of the left ventricle The liver is fatty; the spleen presents various appearances, but generally is shrunken; the pancreas is normal, as are the suprarenals; the stomach shows chronic gastritis; the jejunum and ileum are usually contracted; and the mucosa is often dark red in colour, and marked by small hæmorrhagic points, which indicate the position of the bites. The ancylostomes may be found in large numbers, or may require considerable looking for. Sometimes they are firmly attached to the mucosæ. The kidneys are usually enlarged, pale, and fatty.

Symptomatology. The first stage or invasion of the body by the embryos may be marked by dermatitis of various types, papulo-vesicular or pustulo-ulcerative. The dermatitis is generally situated on the soles of the feet, and called by the natives of the West Indies 'mazamorra' (ground-itch), and is also known as 'pani-ghao' and the sore feet of coolies. It is probable, as remarked by Balfour, that the symptoms of the initial dermatitis, urticarial wheals, redness, and itching, are due directly to the larvæ, while the pustular stage is caused by secondary pyogenic infection. The second stage is the development of a leucocytosis and an eosinophilia before the definite disease begins. The third stage is when the anæmia begins to be appreciable.

The patient becomes pale, weak, and dropsical, the pallor being most marked in the conjunctiva of the lower eyelid, which becomes of a peculiar dead-white appearance. The emaciation may be marked, but, on the other hand, it may be concealed by the dropsy. In many cases there is œdema round the ankles, and in others there may be general œdema, with often ascites, œdema of the legs, scrotum, or face. When the ascites is marked, the patient has a protuberant abdomen, and looks at first sight not unlike a person suffering from malarial cachexia or kala-azar. The tongue is said by some observers to have two purplish smears, one on each side of the median line, and to be pigmented, but this in our experience can be seen in normal natives. The appetite may be perverted and geophagy result, and in addition there are signs of dyspepsia due to the chronic gastritis, and there may be nausea, vomiting, heartburn, and pain over the pit of the stomach. The bowels may be constipated, or there may be diarrhœa. Ova of *Ascaris* and *Trichuris*, together with those of *Ancylostoma*, are often seen in the fæces. Occasionally a little blood and mucus are present, and Charcot-Leyden crystals may also occur.

Blood.—There is marked anæmia, which has been shown by Boycott and Haldane, by using Haldane and Lorrain-Smith's method of estimating the total volume of the blood, to be due to a hydræmia; that is to say, the total volume of the blood is increased without a corresponding increase in the cellular elements and hæmoglobin. This is analogous to the blood condition found in chlorosis, and is the reverse of that found in pernicious anæmia, the features of which are very rarely met with in ankylostomiasis.

The counts given by different observers vary. Thus, Ashford gives as the average of nineteen cases the following figures: Erythrocytes, 1,776,000, hæmoglobin, 21 per cent.; colour-index, 0·6; leucocytes, 7,000; eosinophiles, 10·3 per cent. Boycott and Haldane in seventeen cases found erythrocytes from 4,072,000 to 1,533,000; hæmoglobin from 58 to 17 per cent.; colour-index from 0·71 to 0·56, leucocytes from 44,800 to 3,800; polymorphonuclears, 48·7 per cent.; lymphocytes, 14·4 per cent., mononuclears, 5·9 per cent.; transitionals, 7·4 per cent.; eosinophiles, 23 per cent.; mast cells, 0·6 per cent. Ashford, King, and Gutierrez found erythrocytes from normal to 754,000; hæmoglobin from 8 to 101 per cent., leucocytes from 5,000 to 10,000; polymorphonuclears, 54·5 per cent.; lymphocytes, 16·3 per cent.; mononuclears, 8·6 per cent.; eosinophiles, 17·1 per cent.; other forms, 3·5 per cent.

The red cells may show pathological changes and poikilocytes; megalocytes and polychromasia may be seen, as well as normoblasts and megaloblasts. The diminution of the colour-index is said to be the first pathological sign in the blood. In some very rare cases a condition of hyperglobulia has been observed instead of the usual oligocythæmia.

Boycott has shown that the principal leucocytic changes are to be seen in the blood before a condition of marked anæmia has set in, when it is found that there may be high leucocytosis—20,600 to 56,000—with a very high eosinophile figure of 56·2 to 66·2 per cent., while the hæmoglobin was from 98 to 80 per cent. When anæmia sets in, a leucocytosis is much less frequent, being met with in cases in which anæmia develops quickly. On the other hand, a leucopenia may be seen if the case is very anæmic. The reason for this alteration from a high state of leucocytosis without anæmia to that of leucopenia with severe anæmia might at first sight be thought to be explicable by the hydræmia producing the anæmia. Boycott, however, considers that this is not so, for he points out that leucocytosis can occur with marked anæmia, and that there is always a tendency on the part of the blood to restore its average volume and composition when altered from the normal, and comparing the normal leucocytic count of the hydræmia of chlorosis, says that, if there was no other factor, the leucocytic count of ankylostomiasis would not be affected by the hydræmia.

He thinks that the true explanation is probably exhaustion of the bone-marrow produced by the anæmia, and that it is partially due to a failure on the part of the individual to react to the stimulus to produce the eosinophile leucocytes. In any case, the leucocytic reaction does not bear any relationship to the anæmia. According to Boycott and Haldane, if the eosinophiles are deducted from the total number of the leucocytes, and the percentage of the remainder then calculated, it will be found to be nearly normal. The eosinophilia has been found to remain after the ova have quite disappeared from the fæces. Any inflammatory complication which leads to a polymorphonuclear increase may hide the true eosinophilia. The leucocytes are normal in structure, a few neutrophile, but no eosinophile myelocytes are to be seen. Wemberg and Mello have shown that the injection into guinea-pigs of extracts of various worms induces a certain degree of eosinophilia.

Reviewing this description of the blood, we would point out that it looks as though toxins were stimulating the production of the eosinophiles, and at the same time preventing a proper formation of hæmoglobin, and finally producing the hydræmia. We must state, however, that occasionally we have come across severe cases showing no eosinophilia. Low has demonstrated that eosinophilia is generally well marked in children, while it may be absent in adults, and suggests that the eosinophiles, which are tissue cells at first, come into the blood in response to some stimulus set up by the infection, but gradually disappear as this stimulus weakens with the prolongation of the infection. As a result of the diminution of the production of hæmoglobin, the iron in the liver is diminished.

Patients often complain of palpitation or difficulty in breathing. The lungs will be found normal, but the heart may be displaced downwards and to the left, and be feeble, with a hæmic bruit at the base. The vessels of the neck may be seen to pulsate markedly. The pulse is quick, and may be weak, thready, dicrotic, and intermittent. The liver is very often enlarged, especially in children.

Fever.—Fever in ankylostomiasis was described years ago by Manson, Fernando, and others, and more recently attention has been called to it by Gabbi and one of us. In some cases there is no fever, while in others this feature is present. In our experience three types of ankylostomiasis fever may be met with:—

1. The low intermittent type, which is the commonest, and in which the temperature seldom rises above 100° F.

2. An irregular type, at times intermittent, and at times subcontinuous.

3. An undulating type. This is very rarely observed.

Great care should be taken in making the diagnosis of ankylostomiasis fever to exclude other conditions—*e.g.*, malaria, Malta fever, kala-azar, trypanosomiasis, etc. There is much diversity of opinion on the origin of this fever. In our experience the fever is not due to the worm itself. It is of bacterial origin, being probably due to infections by intestinal bacteria entering the general circulation through the small wounds produced in the intestinal mucosa by the worm. The term 'ancylostoma fever' is, therefore, not quite appropriate. In several cases the fever continues long after the patient has got rid of the ancylostomes by adequate treatment.

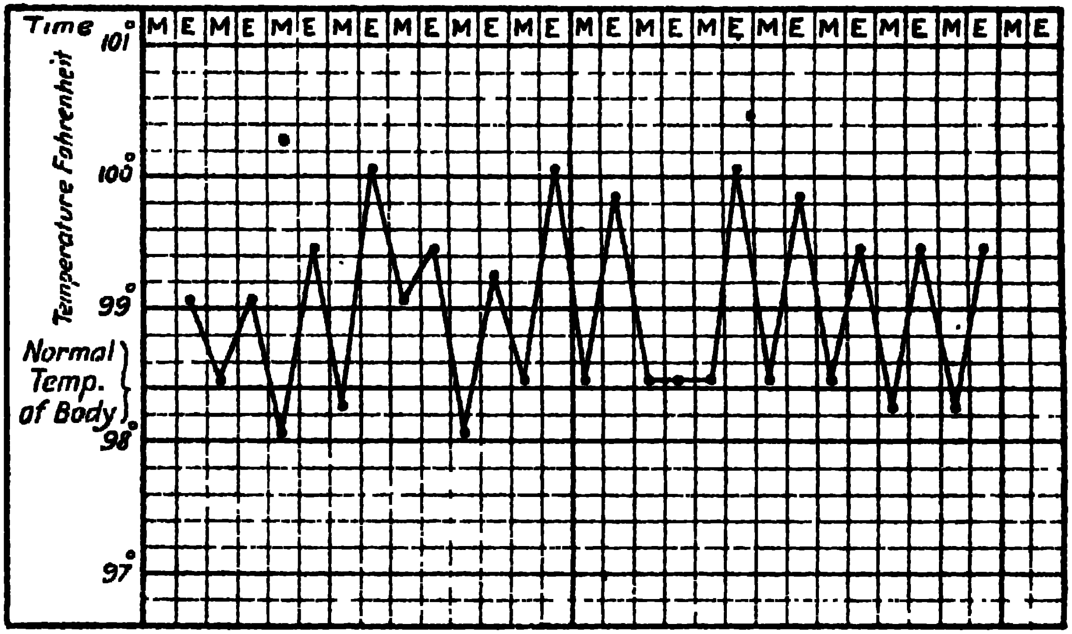

Fig. 756.—Temperature Chart of a Case of Ankylostomiasis Fever.
(From a case in the Clinic for Tropical Diseases, Colombo.)

Urine.—The urine is copious, pale, and often alkaline, with a specific gravity varying from 1010 to 1015. Albumen is rarely seen, but there is an increase of indigo-blue and urobilin, and there is albumosuria at times. The excretion of nitrogen is said to be much increased. Lussana believes that there are toxins in the urine which can be separated by the following method: The urine is condensed in a water-bath at 60° to 70° C. to a syrup, and then extracted with absolute alcohol, which is driven off, and the residue dissolved in sterilized water, and injected subcutaneously into rabbits. This is believed to produce diminution of the red corpuscles, loss of hæmoglobin, and poikilocytosis, which speedily disappear on stopping the injections. These findings of Lussana have been confirmed by some and refuted by other observers.

Mental and physical hebetude are marked, and other nervous symptoms may be observed. Children do not develop properly, and sterility, with delayed menstruation, has been noted.

When the anæmia becomes profound death may ensue from cardiac failure, but any intercurrent affection hastens the end in a case of ankylostomiasis.

Complications.—Any intercurrent disease is a serious complication, as also is pregnancy.

Diagnosis.—The definite diagnosis depends upon finding the ova in the fæces.

Anæmia in tropical countries, especially if associated with dropsy, should at once lead the practitioner to suspect ankylostomiasis. It must be remembered, however, that it is by no means easy to find the ova in the fæces at the first examination, and that sometimes, even in the worst cases, they require to be looked for on several days. Occasionally it is useful to give an aperient to make the eggs appear in the stools.

To facilitate the search for the eggs in the stools several methods have been elaborated by Fulleborn, Pepper, and others. *Pepper's method* is based on the stickiness of the ova; a portion of the sedimented fæces is placed on a slide for a few minutes, and then gently immersed in water; after this, although all other materials are washed away, the ova still adhere to the slide. If this process is repeated several times, numerous eggs may accumulate on the slide. It is to be noted that eggs of *Ascaris*, *Trichuris*, etc., do not possess this physical property, and therefore do not remain on the slide.

Telemann's method is to shake up a small portion of fæces with equal parts of ether and hydrochloric acid, filter, centrifuge, and examine the bottom deposit.

Bass's method is to dilute the fæces with ten or more times their bulk of water, strain through two or three layers of gauze in a funnel, centrifuge, pour off fluid, fill up with diluted fæces, shake, centrifuge, repeat a third time, then examine deposit removed by a clear pipette.

It must be admitted, as noted by Miss Porter and other observers, that concentration methods for the detection of ova are of relatively little use, as in practice they take too long.

Prognosis.—There is no doubt that ankylostomiasis is one of the great factors in producing the death-rate of a tropical native community, very often because it is not diagnosed. Ashford, King, and Gutierrez placed the deaths of Porto Rico caused by ankylostomiasis at 30 per cent. of the total death-rate, and we are not at all surprised at this, for our experience indicates that the disease is frequently entered in death certificates as anæmia, general dropsy, and malarial cachexia.

Treatment.—The aim of the treatment is to kill and remove the parasites, and this can be effected by thymol, eucalyptus oil, eucalyptol, beta-naphthol, or male-fern. A case must not be considered cured until the fæces show no ova on repeated examination after two or three weeks.

In all cases the patient should be carefully examined as to the condition of all his organs before treatment is begun, and should be placed on low or liquid diet for a day or so, and while being treated should be kept in bed, and care taken that the bowels have been well opened.

Thymol, introduced by Bozzolo, should be given in cachets, or as an emulsion. Generally 15 to 30 grains are given, and two hours later another 15 to 30 grains, followed in some cases by a third dose of 15 to 30 grains after another two hours. If the bowels do not act within four hours of the last dose, a saline aperient should be given. The treatment may be repeated on the following day. Another method is to give 10 grains in cachets at night until the desired result is attained. Yet another method, recommended by the International Health Board, is to mix it with an equal quantity of bicarbonate of soda, as this addition is believed to aid the cure and prevent unpleasant symptoms.

Thymol is a very poisonous drug in large doses, causing first irritation of the cerebral centres, with excitement and vertigo, while a dark colour may appear in the urine, or, according to Blum, may be produced by the addition of hydrochloric acid to the urine. According to the same authority, this colour exists in the form of a chromogen in the urine, the chemical nature of which is threefold: thymolsulphuric acid, thymolhydrochinon sulphuric acid, and thymolglycuric acid. In larger doses the nerve centres are paralyzed, the blood-pressure falls, and the patient dies of collapse.

Thymol, however, is very insoluble in water—only 1 in 1,500 of cold water—but it is easily soluble in alcohol, ether, chloroform, glycerine, and turpentine; hence no alcoholic stimulant whatever must be given to a patient who is to take or has taken thymol, and not merely must care be taken not to order stimulants, but the nurses must be warned of the danger of giving them. Thymol is also soluble in oil. Hence no purgative of castor oil should be ordered after its administration. Thymol certainly should never be given if there is marked visceral disease, nor do we think that it should be given in very profound anaemia—*i.e.*, when the number of red cells is below 1,500,000 per cubic millimetre. It is, however, very satisfactory in its lethal action on the worms, but the treatment must be repeated in many cases in a week, and again repeated if ova are seen in the fæces. Sandwith recommends a hypodermic injection of strychnine before thymol is administered.

Eucalyptus Oil and Chloroform.—A much less dangerous treatment is by oil of eucalyptus and chloroform, which may be preceded by a saline purgative given a few hours earlier.

The usual formula is:—

Olei eucalypti	♏xxx.
Chloroformis	♏xlv.
Olei ricini	ʒx.

One half to be given first thing in the morning, and the other half in half an hour. The chloroform is probably the active principle of this mixture. It does not work as satisfactorily as thymol, but it is safer, and can be used several days in succession. We use it often in children and debilitated adults. We have not seen the alarming symptoms described by some authorities as occurring in children and debilitated subjects. Some physicians prefer eucalyptol instead of the oil of eucalyptus. The difference is that eucalyptol is that portion which passes over between 347° to 351° F. when the oil is being distilled from the leaves.

Chenopodium Oil.—The International Health Board of the Rockfeller Foundation in 1917 stated that this oil was the most effective remedy for the treatment of *ascaris, oxyuris*, and *trichiuris*, but that its utility for the treatment of ankylostomiasis was conflicting, and, further, that it produced at times alarming symptoms and even death.

It is either used alone or with oil of eucalyptus in the proportion of three parts of chenopodium to one part of eucalyptus. The method of administration is to forbid all solid food after midday, to give a purge of Epsom salts at 4 p.m., and then at 6 p.m. the first dose of sugar containing chenopodium; this is continued at hourly or two-hourly intervals until the full dose has been taken, and finally, two hours after the last dose, more than 1 ounce of Epsom salts is taken by an adult and repeated if necessary in another two hours.

The dosage of oil of chenopodium is as follows:

1-2 years of age		..	..	..	2 minims for three doses.		
3-5	,, ,,	..	..	..	3-5	,, ,,	,,
6-10	,, ,,	..	..	.	6-9	,, ,,	,,
11-16	,, ,,	..	..	..	10-13	,, ,,	,,
17-50	,, ,,	..	..	..	14-16	,, ,,	,,
Over 50	,, ,,	..	..	..	12-14	,, ,,	,,

It can be given on sugar or in gelatine capsules. The Epsom salts administered are in a solution of 5 pounds in 5 gallons of water, 4 drachms being given to a child one to five years of age, 8 drachms to one of six to ten years, 12 drachms to one of eleven to fifteen years, 16 drachms to one of sixteen to twenty years, and 24 drachms above that age. Castor oil may be given instead of salts, 2 drachms for a child of one to three years, 3-5 drachms for a child of four to eight years, 6-10 drachms for nine to sixteen years, and above sixteen years 8-16 drachms, while 1½ ounces is considered to be the maximum for a female.

No alcohol or acids are to be ingested for a period of twelve hours antecedent to and after the treatment. Pregnant women should not be treated in this way.

Treatment should be repeated after ten days, and one week after the second course the fæces should be examined microscopically to see whether further medication is necessary, and if so it should be repeated at ten days' intervals according to the microscopical findings.

Beta-naphthol, finely powdered, can be given in cachets in 15 to 20 grain doses, administered in the same manner as thymol—viz., one cachet every two hours for two or three times, with the same precautions as with thymol. The patients often complain of severe burning of the stomach after taking them. The drug should *never* be given to individuals suffering from diseases of the kidneys, as it may cause fatal hæmorrhagic nephritis.

In debilitated patients beta-naphthol may be given in 5-grain pills made up with pulvis tragacanthæ composita and syrup. One to three pills, according to age, should be administered early in the morning on six successive days. No preliminary preparation is necessary. The results, however, as regards the destruction of the parasites, are not brilliant.

Nicol recommends:—

Beta-naphthol (finely powdered)	ʒiv.
Mucilaginis tragacanthæ	℥i.
Aquæ menthæ piperitæ	ad ℥vi.

of which 6 drachms (gr. xxx. of beta-naphthol) is given to an adult male, 5 drachms to an adult female, and 1 to 2 drachms to children, for a dose. Three doses are given at intervals of two hours. Two hours after the last dose a saline aperient is given. Beta-naphthol does not keep well, and should be stored in ½-pound bottles, and kept in a cool place.

Male fern, followed by castor oil, or calomel, or infusion of senna, has also been strongly recommended, and was generally used before Bozzolo introduced thymol in 1880. The Porto Rico Commission found it useless even in doses which produced toxic symptoms.

Nattan-Larrier recommends the following method of administering *Filix mas*:—

First day: Milk diet and saline purge. Second day: Milk diet; a capsule containing 0·30 centigramme of oil of *Filix mas* every ten minutes until twenty have been taken, followed in one-quarter of an hour by a capsule of ether every three minutes until eight have been taken. After the last capsule, 15 grams of castor oil are administered, and, after half an hour, 25 grammes of castor oil. Third day: A saline purge. Fourth day: Examination of the fæces and repetition of the treatment. Brimont recommends the essence of *Melaleuca viridiflora*.

Worms in the Fæces.—Whatever treatment be adopted its effect must be judged by the worms found on examining all the fæces passed during the first twelve to twenty-four hours after dosage. These fæces are stirred up with water, allowed to settle, and the water decanted, and this process repeated several times, after which the deposit is placed on a flat dish with a black background, and the whitish or greyish little worms looked for.

Treatment of the Skin Eruption.—The area showing the eruption should be painted with a solution of salicylic acid in collodion (1 in 6) in the early stages, or later it should be soaked in a weak solution of carbolic lotion (1 in 100), and the vesicles, pustules, etc., should be opened and cleaned with 1 in 40 carbolic lotion, and the whole area dressed with a carbolic lotion or carbolic ointment dressing. The itching may be relieved by an ointment of salicylic acid gr. v. in ʒii. of zinc oxide ointment and vaseline. The dressing should be performed twice daily, and the internal treatment, as described above, begun at once, and repeated every week for some time.

Treatment of the Mouth.—For about two weeks after infection the patient should use a mild antiseptic gargle several times a day, and should be instructed to spit out his saliva, sputum, etc., and not to swallow it. The gargling should be performed before drinking or eating anything. The sputum should be collected and examined for larvæ.

Prophylaxis.—Prophylaxis must be based upon an attempt to kill the parasites in the human being, and to prevent the infection of the human being by the parasite, but in order to be successful in these methods it is absolutely necessary to educate both the rich and the poor of a district in the essentials of the disease. This must be done by illustrated lectures and pamphlets in the vernacular. An appeal must also be made to the people to come at once for treatment when suffering from skin eruptions or anæmia.

The first method is the most feasible, and has been tried on a large scale at Porto Rico, and on many estates and in mines. The quickest way is to examine the people for anæmia, and treat the anæmics with thymol, the eucalyptus-oil mixture, or β-naphthol, after the examination of the fæces. On estates the method of examining the blood of non-anæmic persons for an eosinophilia might be adopted, as the worms may be present before the anæmia shows itself. The fæces of persons showing eosinophilia should then be examined for ova, and treatment instituted on the findings. Of course a certain degree of eosinophilia is also present in cases of ascariasis and other kinds of helminthiasis.

With regard to the second method, the formation and use of proper latrines may do much. With regard to estates, tea-bushes, etc., should not be allowed to grow right up to the coolies' lines, but a clear area should be left, and this should be treated from time to time with quicklime. Further, every alternate row of bushes might be left out in the half-acre adjoining the lines, and in the vacant spaces latrine-holes lined with lime might be dug. The use of bucket-latrines and the destruction of the fæces in a small crude incinerator would be better, and could be easily managed on estates. The best cheap latrine is 'Bailey's patent,' manufactured by the Empire Engineering Company of Cawnpore, at a cost of 118 rupees for a two-seat, and 300 rupees for an eight-seat latrine.

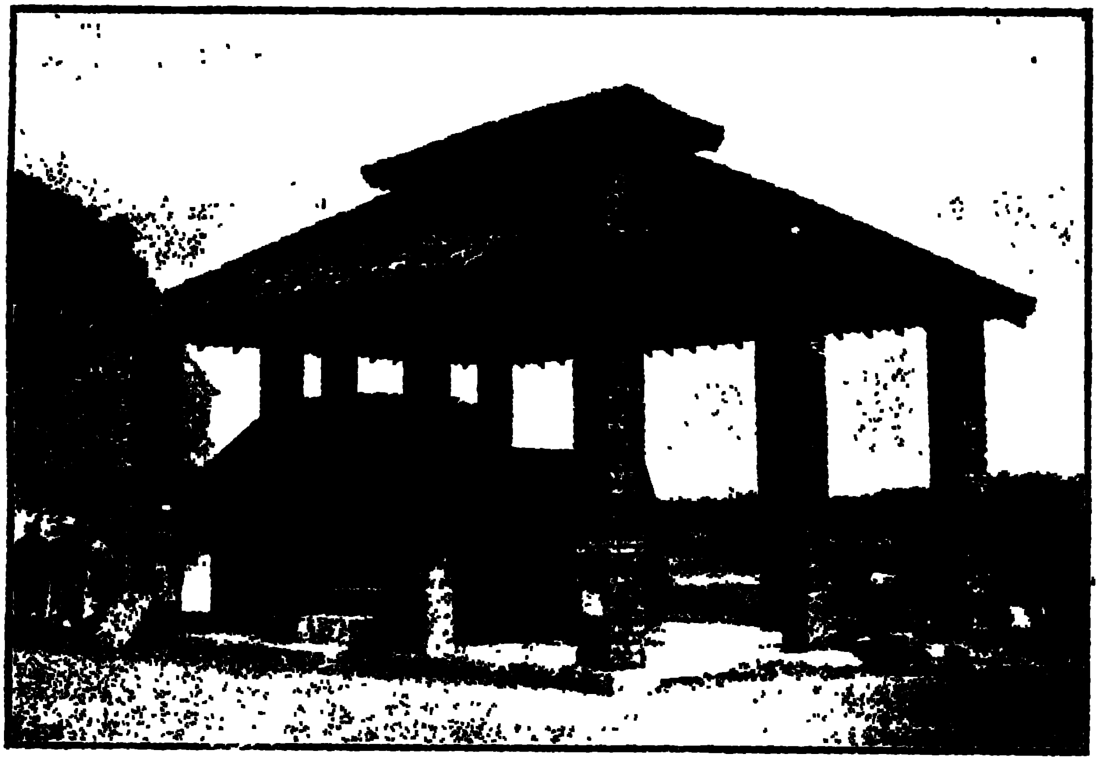

FIG. 757.—A CHEAP AND EASILY CONSTRUCTED INCINERATOR.

Leiper has suggested that fruitful results would be obtained from a more detailed study of the larvicidal effects of chemical manures such as 'nitroline,' etc. According to certain experiments made by this author, it would seem that after treatment with such chemicals human ordure could perhaps be used on the land with safety.

The figures show small incinerators in use in a mill and in a gaol in Colombo, but it must be remembered that fæces require a considerable amount of fuel and a considerable draught before they are properly burnt. There is, however, no need to go to great expense, and a simply constructed incinerator will often work well, if a little smell is not objected to. In order to calculate the size of latrine required, it must be remembered that an Indian community is estimated to pass 8 ounces of fæcal matter per diem in a mixed population of races, sexes, and ages, and 40 ounces of urine. The usual size of a galvanized iron latrine-bucket is 14 inches high by 12 inches broad at the mouth and 9 inches at the base, and it has a cubic capacity of 0·9 cubic foot, and is said to weigh 10 pounds when full. Coir fibre is often mixed with the fæcal matter in the proportion of 2½ pounds of coir to 1 pound of fæcal matter or 1 gallon of urine.

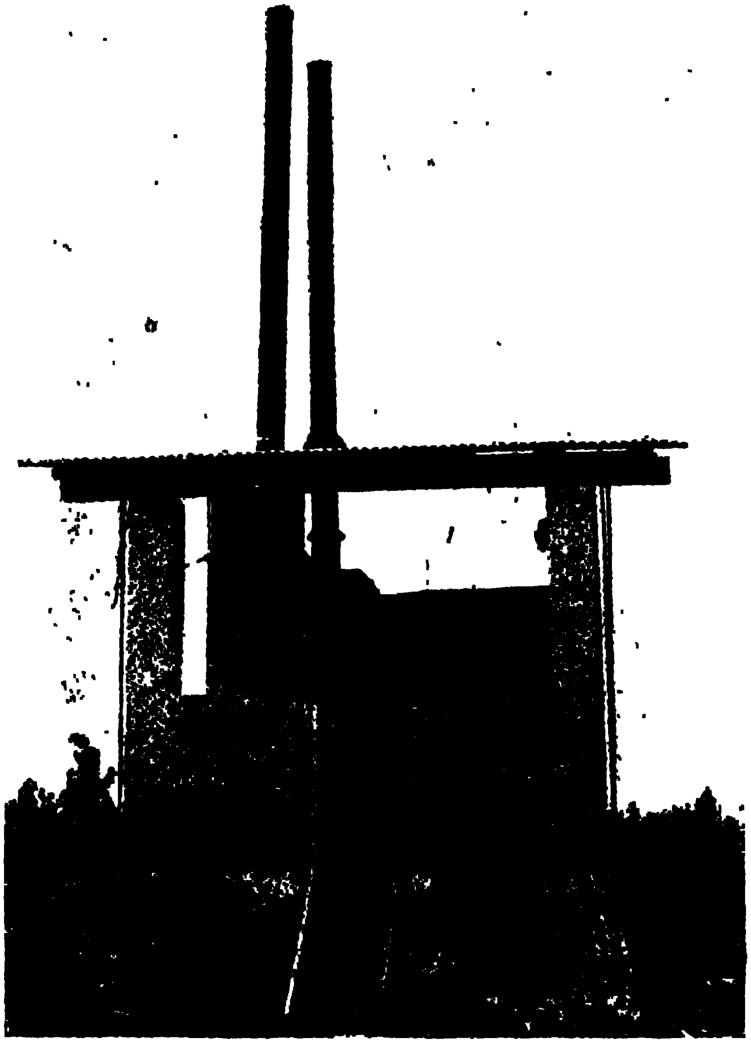

FIG. 758.—ANOTHER CHEAP AND EASILY CONSTRUCTED INCINERATOR.

Messrs. Freudenberg and Company, of Colombo, use a simple incinerator, and they have kindly supplied us with the following details of their process, which is carried out at night:—

Average number of buckets of fæcal matter burnt per night, 20.
Average weight contents of a bucket, 26 pounds.
Average quantity of ash left after burning the above, 5 buckets.
Average amount of coir dust used per bucket, 2 pounds.
Average amount of firewood used per burning, 2 hundredweight.
Average amount of rubbish burnt at the same time, together with a few old gunny bags, 1½ hundredweight.
Average number of coolies whose fæcal matter is dealt with, 400.
Latrine coolies at 62½ cents per diem to do the work, 2.
Firing starts at 7 p.m., and is finished by 8 a.m.; the highest temperature recorded was 1,050° C.

The urine can, of course, be separated from the fæces by using a Donaldson's separator latrine. The urine can then be disposed of by burial, and the fæces burnt.

There is no doubt that some such method would have excellent results in dealing with the problem in small communities and estates if carried out properly.

Badly infected lands might be treated with lime. It has been recommended that coolies should protect their feet by first dipping them in a bucket of tar, and then in one with sand.

The method of dealing with a large community is best exemplified by quoting the excellent work of the two Porto Rico Commissions, temporary and permanent, the former consisting of Ashford, King, and Igaravdez, and the latter of Igaravdez, Martinez, and Sein y Sein.

Patients attend at a central, or one of the outlying depots or dispensaries, where their stools are examined, and they are given medicines, and a card with the following instructions

1. Take one of the two purgatives given to you to-night (sodium sulphate).
2. Take at 6 a.m to-morrow half the capsules [all the capsules equal 45 to 60 grains (3 to 4 grammes) of thymol, or 23 to 45 grains (1·5 to 3 grammes) of β-naphthol].
3. Take the other half at 8 a.m the same morning.
4. Take the other purgative at 10 a.m.
5. You should neither drink wine nor any alcoholic liquor during the time you are taking these medicines.
6. Come for more medicines until the physician says you are cured.
7. Have a privy in your house. Do not defæcate on the surface of the ground, but in the privy.
8. Do not walk barefooted, so that you may avoid catching mazamorra in your feet. Wear shoes, and you will never suffer from anæmia.

In addition, farmers were requested to stop the pollution of the ground, and to introduce the use of shoes

The result was that 11 per cent of the population were treated in the year 1906-07 (89,233), and of these, 25·7 per cent. were cured, 17·4 per cent. practically cured, 40·5 per cent. were under treatment, 16·2 per cent. ceased to return, and 0·2 per cent. died, at a total cost of £9,600, of which £7,200 went in salaries and £1,100 in drugs.

Again, the highest credit must be given to the Americans for the fearless way in which they spend money on the prevention of disease and the free hand which they give to the sanatarian in the tropics.

In mines Oliver recommends that a solution of iron sulphate be used as a wash for the floors.

Salt has also been recommended by Perroncito, and later by other observers, but as a solution of at least 2 per cent. is necessary to kill the larvæ, this method is too expensive.

SUMMARY OF PREVENTIVE MEASURES.

Educational :—

Instruction of rich and poor with regard to the methods of infection, symptoms, treatment, and prophylaxis.

Personal Prophylaxis :—

1. Protection of the feet.
2. Protection of the hands.
3. Immediate treatment of the eruption on feet or hands.
4. Necessity of early treatment.

Public Prophylaxis :—

1. Search for and treatment of carriers.
2. Search for cases of the skin eruption and treatment of the same.
3. Search for cases of anæmia and treatment of same.
4. Provision of sanitary conveniences kept in good condition, and associated with a good system of conservancy.

Ascariasis.

Definition.—Ascariasis is infection with *Ascaris lumbricoides* Linnæus, 1758; *Toxascaris canis* Werner, 1782: or *Belascaris mystax* Zeder, 1800, the first named being much the most common.

Symptomatology.—The symptoms may be nil, or may resemble those of cestode infections, being partly gastro intestinal, partly reflex, while skin irritation and eruptions may also be present. If, however, the number of parasites be very considerable, signs of toxic poisoning, or even of intestinal obstruction from interlacing of the worms, may develop, but the great danger is from the wandering of the parasites. If they wander up the bile-duct and into the liver, they may cause abscesses in the liver. We have found as many as eleven worms in the bile-duct, with a large number in the liver, three of which lay in abscess cavities. They may also enter the duct of Wirsung, and cause slight inflammation of the pancreas, or go into the appendix, and cause appendicitis. Further, they may pierce the bowel in cases of ulcerative conditions of the bowels, and enter the peritoneum or the bladder, or enter the lung, the nose, or the ear by the Eustachian tube—in fact, they may wander all over the body. The observer must, however, be careful to distinguish between the post-mortem and ante-mortem wanderings of these worms: in the former case the worms are generally found alive. The most important reflex symptoms are the convulsions so commonly met with in children, and attacks of so-called 'wormy' cough are not rare. We have seen cases of fever resembling typhoid (typho-lumbricosis) which on post-mortem examination have shown no lesions of typhoid, but enormous numbers of ascaris.

Diagnosis.—The diagnosis will depend upon the discovery of the eggs in the fæces.

Treatment.—The best treatment is santonin, with some form of purgative. Usually santonin is mixed with an equal quantity of calomel, and given in doses of 1 to 3 grains for an adult, and $\frac{1}{6}$ grain for every year of life for a child. The dose is given every morning for two or three days, and repeated again in a week if eggs still appear in the fæces. It is as well to remember that santonin may cause blue or yellow vision.

Oil of chenopodium may be given in gelatine capsules or in castor oil. (For dosage see p. 1770.) In China *Quisqualis indica* is at times used: 2 drachms of the powder.

Oxyuriasis.

Definition.—Oxyuriasis is infection with *Oxyuris vermicularis* Linnæus, 1767 (see p. 857), and is common all over the world.

Symptomatology.– The symptoms are irritation in the region of the anus, with sometimes a distinct entero-colitis, and sometimes slight fever. It is usually stated that there is a sense of irritation in the nose. The diagnosis is to be made by finding the worms in the motions after a purgative. In girls the worms may enter the vagina and cause vaginitis.

Treatment.– The gravid females can be killed by rectal injections of quassia, alum (ʒi. to a pint), salt (ʒii. to a pint), but the young forms require internal treatment with santonin and calomel, as described under Ascariasis. Flynn recommends sulphur (gr. iii.) three times a day in adults, and gr. i.ss. in children, given as a cachet or lozenge. A 10 to 20 per cent. calomel ointment, diluted unguentum hydrargyri (1 in 4), may be applied to the anus, or iodoform and naphthalin suppositories may be used.

Intestinal Polyparasitism.

Definition.—Intestinal polyparasitism is the invasion of the alimentary canal by more than one species of parasite.

Remarks.– We have, since 1903, investigated the question as to which parasites are commonly present in natives of tropical Africa and Ceylon, and find that it is the rule rather than the exception for their intestines to harbour more than one species of parasite.

Statistical information with regard to the prevalence of the various forms in different tropical regions is still wanting, but some valuable observations have been made, especially in the Philippine Islands by Garrison, and in South Africa by Miss Porter. The relative prevalence of the various intestinal parasites in the Philippines has been carefully studied by Garrison, who finds that 84 per cent. of the investigated persons were infected with fifteen genera and about twenty species, multiple infections being the rule, the average number of infections being 2·25 per head.

The prevalence of the various parasites were as follows:—

	Per Cent.
Trichuris	59·0
Ancylostoma and Necator	52·0
Ascaris	26·0
Amœbæ	23·0
Flagellates and Ciliates	21·0
Strongyloides	3·0
Oxyuris	0·8
Tænia	0·7
Schistosoma japonicum	0·6
Paragonimus	0·4
Opisthorchis	0·2
Hymenolepsis	0·1

Besides these, however, there were a number of undetermined forms. The infection with *Trichuris* is variously given in different countries—*e.g.*, Porto Rico (Commission), 7·27 per cent.; India (Fearnside), 6·95 per cent.; India (Dobson), 4·4 per cent.; Central Africa (Daniels), 2·79 per cent. The infection with *Ancylostoma* and *Necator* is given in India (Calvert), 83 per cent.; (Dobson), 57·58 per cent.; (Fearnside), 65·83 per cent. *Ascaris* infection in West Africa (Wellman) is 50·97 per cent. Garrison considers his figure of 26 per cent., which is based upon adults only, as much too low. *Strongyloides* is placed in Central Africa at (Daniels) 1·5 per cent.; West Africa (Wellman), 0·65 per cent.; Porto Rico (Commission), 0·8 per cent. *Oxyuris* is given in India (Dobson) at 15·37 per cent.

Ætiology.—*Ascaris lumbricoides* is, in our experience, by far the most common parasite, and it is often associated with either *Trichuris trichiura* or *Necator americanus* (or *Ancylostoma duodenale*) in double infections, but triple infections with these three parasites are not uncommon, and quadruple infections of the three associated with *Strongyloides intestinalis* are also common.

Associated with one or more of these worms it is by no means unusual to find *Loeschiæ* and flagellates, especially *Trichomonas hominis*, and more rarely ciliates—*e.g.*, *Balantidium coli*. *Oxyuris vermicularis* is fairly common in children, but tapeworms are not so frequently met with in Ceylon, India, and Equatorial Africa, while they are extremely common in Abyssinia.

In China and other countries *Trematode* infections must also be considered, and in the West Indies and Africa infection with *Schistosoma mansoni*.

Symptomatology.—The symptoms presented by the patients may be nil if the parasites are few in number, and will in any case depend mostly upon the action of that species which is known to be the more pathogenic or which is most abundant, but it may be very difficult or impossible to separate the symptoms caused by one parasite from those due to another. Cases may show signs of fever, anaemia, diarrhœa, and even dysenteric symptoms may appear if the infection is heavy.

Treatment.—The treatment must commence with that laid down for the parasite which is the more important from a pathogenic point of view—*e.g.*, in the case of a double infection with *Ancylostoma* and *Ascaris*, the ankylostomiasis must be treated first and then the ascariasis.

Rare Infections.

Gordiaceiasis and Acanthocephaliasis (see pp. 678 and [illegible]).

Infections with species of the Gordiacea and Acanthocephala are rare. Treatment would be on the same lines as for ascariasis.

Intestinal Diplopodiasis and Chilopodiasis (see pp. 689 and 739).

Diplopodiasis and chilopodiasis are rare and unimportant, giving rise to intestinal pains and diarrhœa. The diagnosis is only possible on discovery of the parasites in the fæces. The treatment is the chloroform mixture, as for ankylostomiasis.

These infestations are placed here only for convenience.

Ascariasis.

CHAPTER LXXVI

SPRUE AND OTHER DIARRHŒAS

Sprue—Pseudo-Sprue—Hill diarrhœa—Low-country morning diarrhœa—Flagellate diarrhœa—Famine diarrhœa—Cœliac disease—References.

SPRUE.

Synonyms.—Ceylon sore mouth, Aphthoides Chronica, Tropical aphthæ, Impetigo Primarum Viarum, Diarrhœa Alba, Psilosis Linguæ et Mucosæ Intestini, Phthisis Abdominalis, Blastomycosis Intestinalis, Endemic diarrhœa, Cochin China diarrhœa.

The term 'sprue' (sprew, sprau, sprulf, spru, spre, spree, spro) is a phrase used in Holland and Scotland for aphthous stomatitis in children, Aphthæ tropicalis der deutschen, and was applied to this disease by Manson and Van der Burg, the latter calling the disease in Batavia 'Indische spruw.'

Definition.—Sprue is a chronic catarrhal inflammation of the alimentary canal, of unknown cause, characterized by a peculiar ulcerative condition of the tongue and mouth, and by the passage of large, pale, frothy motions, the symptoms waxing and waning periodically.

History.—According to Hiatt, sprue was first mentioned in the writings of John Bicknell, in America, in 1737. Hillary, of Barbados, in 1766, in a most remarkably able manner, describes the disease for the first time under the name 'aphthoides chronica.' His account is well worth reading, and there can be no possible doubt that his description refers to the disease we now call sprue. The Indian physicians Twining (1835), Grant (1854), Cunningham (1877), mention symptoms indicating that they were acquainted with a disease of this nature, while Elliott of Ceylon gave a very good account of the malady, which he called 'phthisis abdominalis.'

At the same time—*i.e.*, 1864 to 1883—French physicians noted a peculiar form of diarrhœa, commonly met with in Cochin China, which perplexed them considerably, a large number believing that it was dysenteric in nature, while others considered that it was probably a new disease.

In 1880 Manson was the first after Hillary to clearly define the disease, which he called 'sprue'; and in the same year, and independently, Van der Burg described it under the term 'Indische spruw' in Batavia. In the next year (1881) Sir Joseph Fayrer delivered the Lettsomian Lectures on chronic white tropical diarrhœa. These three authors permanently established the disease as a clinical entity. Since then many important papers and articles have appeared, notably Roux's 'Traité' in 1888, Thin's 'Psilosis' in 1897, and Cantlie's papers, and the publications by Brown, Begg, Castellani, Low, Bahr, Ashford, Rogers, Nicholls and many others.

Climatology.—The endemic home of sprue appears to be Asia; especially Malaya, Sumatra, Java, Siam, and Annam; but it also extends into Burma, India and Ceylon, China, Australia (East and South), New Caledonia, the Fiji Islands, and Japan. Possibly it exists in the West Indies, where Hillary originally described it, and it may occur all through the tropics; but if so, it must be rare in certain regions—as, for example, West Africa. Rare cases of sprue occur in Europe.

Ætiology.—The etiology of sprue has not yet been elucidated, but of the many etiological theories brought forward, the one which at the present time receives more acceptance is the monilia or oidium theory, also known as *Kohlbrugge's theory*. Kohlbrugge, in 1901, found in cases of sprue in Java a fungus which he identified with *Monilia albicans* Robin, at that time better known under the name of *Oidium albicans*. He made a very complete histological study of one of his cases which ended fatally, and emphasized the fact that the fungus in sections of the tongue, etc., had invaded the deep strata of the mucosa, the glands, and portions of the submucosa. He concluded that the fungus was the cause of the disease. Kohlbrugge's findings were speedily confirmed by many observers, especially French and Dutch, and Le Dantec gave to the malady the name of *blastomycosis intestinalis*.

In 1905 and 1912 cases of sprue with presence of monilia fungi were placed on record by Castellani, who, in 1912, described several species, *Monilia intestinalis*, *M. enterica*, etc. This author's opinion was that such fungi were the cause of some of the symptoms of sprue, as, for instance, the frothy appearance of the stools, but doubted their being the primary cause of the malady. He believed them to be the cause of the frothy diarrhœa, because he had noted that this symptom generally improved after large doses of bicarbonate of soda. He thought that sodium bicarbonate given in large doses might decrease the acidity of the intestinal contents, and in this way check the growth of fungi, which, as is well known, grow better on acid than on alkaline media. In 1913 Castellani and Low described a new monilia found in a case of sprue, *M. decolorans* Castellani and Low, 1913. They came to the conclusion that this and other monilias (*M. intestinalis*, etc.) were the cause of certain important symptoms of the disease such as frothiness of the stools, etc., but they were not inclined to consider them to be the primary cause of the malady: they quoted in analogy the example of scabies, in which the main part of the symptoms is due to the secondary invasion by staphylococci, and not to the primary cause, the acarus.

In 1914, Bahr, in a series of interesting publications, supported Kohlbrugge's theory, believing that the cause of the malady was probably *Monilia albicans* Robin.

From 1915, Ashford, in several able papers, has supported the same theory, though he does not consider that *M. albicans* is the cause of the malady. He calls the monilia observed in his cases *M. psilosis*, but, according to the laws of nomenclature, the correct term would seem to be *Monilia enterica*.

Monilias found in Sprue.- The principal species of monilia so far found in sprue are the following.

1. *Monilia albicans* Robin.
2. *Monilia decolorans* Castellani and Low.
3. *Monilia intestinalis* Castellani.
4. *Monilia fæcalis* Castellani.
5. *Monilia insolita* Castellani
6. *Monilia tropicalis* Castellani.
7. *Monilia enterica* Castellani (probable synonyms: *Monilia psilosis* Ashford, *Parasaccharomyces ashfordi* Anderson).

For description of these fungi see p. 1079.

Species of the Genus Oidium found in Sprue. - The principal species of the genus *Oidium sensu stricto* so far found in sprue are:—

Oidium rotundatum Castellani.
Oidium asteroides Castellani.

For description of these fungi see p. 1093.

Remarks.—Kohlbrugge's theory is the one finding most support at the present time, and, according to various authors, agglutination and complement fixation tests are supporting it, and certain observers have claimed to have succeeded in reproducing the malady in the lower animals by injection of intestinal monilias. We believe that if the malady is eventually demonstrated to be a moniliasis, then a group of monilias, and not one only, will be found to be capable of producing the affection: this in analogy to what one sees in bacillary dysentery, and in affections due to the higher fungi, such as ringworm

It must be noted that fungi, especially in tropical countries, may be found also in stools of normal individuals and persons suffering with affections which are not connected with sprue. Such fungi mostly belong to the genera Monilia, Saccharomyces, Cryptococcus, Willia, Mycoderma, Oidium.

The Helminthic Theory. Some authorities consider *Strongyloides stercoralis* to be the cause of the disease, but in our experience the worm has nothing to do with the malady, being found in all sorts of pathological conditions.

The Bacterial Theory.- Numerous different cocci, bacilli, etc., have been described as the causative agents of sprue, but so far none has been demonstrated to be the primary cause of the malady. Rogers and Nicholls have suggested that the disease may be a *streptococcal infection*, both authors having obtained good results by using streptococcal vaccines. The streptococci found by Nicholls were of the viridans type, as found also in normal mouths. Complement fixation tests carried out by Nicholls would seem to support the streptococcal theory. Nicholls believes the etiology to be in reality twofold, there being an infection factor and a dietary factor.

Attention must be called to certain cases of pseudo-sprue, described by one of us, and due to a bacillus of the Flexner group. These cases are not true sprue, as they get well either spontaneously without leaving the tropics or by a course of vaccine treatment prepared with the Flexner-like bacilli isolated from the stools.

The Protozoan Theory. Various protozoan organisms have been found in cases of sprue, amoebae, spirochaetes, flagellates, etc., but none have been demonstrated to be the cause of the malady.

The Climatic Theory. This does not need to be discussed, though a hot damp climate is an important predisposing cause.

The Food Theory.—This also does not need to be discussed, though spicy foods and alcohol may be predisposing causes, and dietary errors, as emphasized by Nicholls, may lower the resistance of the alimentary mucosa to germ infection.

The Deficiency Theory.—This theory has been ably brought forward by Cantlie, who noticed in certain cases signs of scurvy.

Syndrome Theory. Finally, the theory must be mentioned according to which sprue is not a separate disease, but is a syndrome met with in various pathological conditions, such as chronic dysentery and pernicious anaemia. This theory is not supported by any medical man of long tropical experience. The disease presents typical symptoms and a typical course, but, as in dysentery, so in sprue, it is in our opinion probable that the clinical term covers several closely allied conditions, e.g., it is possible that there may be a sprue of hyphomycetic origin, a sprue of bacterial origin, and a sprue of protozoan origin.

Pathology.—With an unknown causation, it is not easy to write an account of the pathology. It would appear as though the primary lesions are beneath the epithelium in both the tongue and the intestine, and cause the superficial desquamation and catarrh. In the intestine the disease begins with submucous congestion, after which follows thrombosis of the vessels, and exudation of haemoglobin, and a round-celled infiltration. The mucosa suffers because its blood supply is damaged, and therefore necrosis takes place, the glands and villi being affected. The oesophagus and stomach also suffer. The liver is at first enlarged and congested, but later becomes atrophied and small. The fact that the tongue, oesophagus, stomach, and intestines are affected would indicate that something deleterious is being carried by the blood stream to these organs, rather than that something is acting from the surface. The irritation of the liver may be due to the same cause.

When once the mucosae are damaged, the chemical processes of digestion and the absorption of their products must be interfered with; while at the same time the absorption of poisons from the alimentary canal must be easier. Indeed, there is evidence of this in the increase of indigo blue in the urine, which is at times marked.

These two conditions would lead to an atrophy of the liver, which organ is one of the great safeguards against a toxæmia of intestinal origin. When the liver is sufficiently damaged, a toxæmia is possible, and occurs; hence, possibly, the advantage of the treatment by liver-soup or other preparations of liver.

The damaged condition of the mucosa of the mouth and tongue makes mastication difficult. The denuded condition of the œsophagus causes the burning pain during swallowing; the condition of gastric and intestinal mucosæ causes the dyspepsia and diarrhœa of the disease. The diarrhœa is characterized by pale, frothy motions, the explanation of which is as follows:—

On opening the bowels post mortem, the observer is struck by the fact that, though there may be plenty of bile in the duodenum and in the higher portions of the bowel, this gradually disappears until, in the lower parts of the small intestine, the contents appear white. In normal fæces bilirubin should be changed into stercobilin (hydrobilirubin), which is urobilin, and is identical with that found in the urine. The white appearance of the intestinal contents is probably partly due to certain bacteria, especially *B. albofaciens*.

Vaughan Harley has shown that in the upper third of the small intestine the normal fæces are of a yellowish colour, due to bilirubin. In the middle third they are of a whitish or greyish colour, probably owing to the bile-pigments being converted into chromogens, which become green in the lower third. After passing the ileo-cæcal valve, the bile-pigments are converted into urobilin by the action of putrefactive bacteria, but a considerable quantity of this is in the form of a chromogen. If the pancreatic juice is absent a colourless form of urobilin is found, called leuco-urobilin; the blood pictures in the last stage closely resemble that of pernicious anæmia. A very common feature is the presence of true chromatin granules in certain red cells.

Histopathology.—The histopathology of the disease requires much further study. The principal histopathological feature of the malady is a severe process of desquamation of the mucosæ of the digestive tract, together with atrophic changes of the mucosæ, glands, pancreas, and liver. One of us, in association with E. H. Ross, Low, and Cropper, has studied certain histological features of the epithelial cells of the tongue and the condition of the blood.

Changes in the Epithelial Cells of the Tongue.—These cells present often a fatty degeneration, but an interesting feature is the great increase in the presence of certain inclusions, which, as demonstrated by one of us, may be found also in various kinds of stomatitis, including the usual tobacco variety, and even in normal people. These peculiar inclusions are of two types.

Type I.—This is by far the commoner. The cell presents a various number—one to twelve or fifteen—of roundish or oval formations of variable size, 2 or 8 μ in diameter, which in preparations coloured by Leishman's stain take up a reddish or purplish colour. They are apparently structureless, but they may present one or two small vacuoles. These inclusions stain beautifully by using H. C. Ross's jelly method, but even with this method do not show any structure. They are not fat drops, as they colour deeply with Leishman's stain instead of becoming dissolved in the alcohol. They do not appear to be of nuclear substance, as the masses are structureless. They do not seem to be parasitic, as they are structureless and homogeneous. The severer the inflammation of the tongue, whatever the cause, the more numerous are these bodies. The greatest probability is that they are merely masses of keratohyalin.

Type II.—Occasionally instead of structureless homogeneous masses, granular agglomerations somewhat resembling chlamydozoa are seen. Whether these are a stage of the former inclusions is not known, but they appear to be merely cell degenerations.

Changes in the Cells of the Blood.—These have already been mentioned under the heading Pathology.

Morbid Anatomy.—The body is emaciated, and the skin often hangs loosely, and there may be œdema about the ankles. The tongue shows small areas of infiltration into the connective tissue, vesicles, and small ulcers. The filiform papillæ atrophy, and the fungiform papillæ become swollen and prominent. The pillars of the fauces and the tonsils may show subepithelial inflammation, and even suppuration and ulceration. The œsophagus is inflamed, and its mucosa is attenuated in places. The mucosa of the stomach may be pale and atrophied, or rough and cirrhotic. The mucosa of the small intestine may be slightly eroded, or may be so destroyed that the whole bowel is diaphanous with vascular arborizations; or there may be effusion into the solitary and agminated glands. The contents are bile-stained in the upper parts, and whitish lower down. The large bowel may be ulcerated. The liver is atrophied, but otherwise normal. The pancreas may be normal, inflamed, or cirrhotic. The peritoneum may be thickened and chronically inflamed, and in some cases show adhesions. The other organs are normal as a rule, but sometimes they are atrophied.

Symptomatology.—The incubation period of sprue is quite unknown, and the onset is insidious, without marked symptoms, which are usually merely failing strength and an undefined sense of illness. The disease may begin with diarrhœa and intestinal symptoms, or with mouth symptoms only.

Usually it begins with slight attacks of sore mouth, indigestion, and morning diarrhœa, often of a bilious nature; but as none of these are severe, and all are evanescent, the patient thinks little or nothing about them, and does not consult a medical man until the disease is well established. Three symptoms now worry the patient—viz., sore mouth, indigestion, and morning diarrhœa.

On examining the mouth, the dorsum of the tongue will be seen to have a whitish fur, through which the swollen fungiform papillæ are projecting. The sides and tip of the tongue are red and inflamed, with often small vesicles, small ulcers, and bare patches, which are very tender. Similar patches may be noted under the tongue near the frenum, on the inside of the cheeks, on the palate, and on the pillars of the fauces. A little ulcer, called Crombie's molar ulcer, may be seen near the two last upper or lower molar teeth. So tender is the mouth at times that deglutition, mastication, warm or spiced foods, acid or alcoholic liquors, cause much pain. In addition, mucus may be noticed clinging to the pillars of the fauces and to the back of the pharynx. This mucus is a source of great distress to the patient, as it accumulates in considerable quantities especially if some warm fluid has been taken, and the effort to get rid of it makes him almost sick. On swallowing food, a burning pain is felt along the course of the œsophagus and over the sternum, as though there was something raw inside (as, indeed, there is). The voice is said by Thin to be altered at times, but we have not specially noted this.

The neck, thorax, and arms may show signs of emaciation. The abdomen is swollen, sometimes markedly so, especially in the epigastric region, and the wall is soft and relaxed. The patient complains of dyspeptic symptoms, viz., a sensation of discomfort and distension after meals, with acid eructations and sometimes vomiting. Early in the morning he feels symptoms of intestinal discomfort, and passes a few copious, greyish, offensive, frothy motions, and no more for the rest of the day. After these motions he may feel much better, and have a good appetite.

Examination of the fæces shows mucus, epithelial débris, and many bacteria, and often yeast-like fungi, and in some cases eggs of various worms may be present. The quantity of fæces passed varies with each motion, but is in excess of the normal, this being due to solids rather than liquids. The excretion of nitrogen and fat is increased. Fat constitutes over 20 per cent., often 40 to 50 per cent. of the stools, while in normal individuals on a mixed diet it averages 6 to 8 per cent. Some observers believe that this is not due to the fat-splitting enzymes non-acting, but to the absorptive power of the upper parts of the intestine being interfered with.

The analysis of gastric contents may show a decrease in hydrochloric acid and pepsin. The pancreatic juice may show absence of diastase, trypsin, and lipase.

The most complete analysis of urine and fæces has been carried out by V. Harley and Goodbody. The patient, weighing 30·87 kilogrammes, was on a milk diet, containing 12·00 grammes of nitrogen, 70·44 grammes of fat, 82·32 grammes of carbohydrates, and 1,900 c.c. of fluid. The urine passed measured 1,050 c.c., specific gravity 1012, urea 10·8 grammes, uric acid, 0·8 gramme; ammonia, 0·44 gramme, phosphates, 1·27 grammes, chlorides, 3·89 grammes. Total sulphates, 1·47 grammes, of which 1·35 grammes were alkaline and 0·12 aromatic. The average daily quantity of the motions was 255 grammes, of which 70·40 were water, 1·47 nitrogen, 35·92 fat. The nitrogen given in the food was 12·00 grammes, and that in the fæces 1·47 grammes; therefore 88·80 per cent. had been absorbed. The fat in the food was 70·44 grammes, and that in the fæces 35·92 grammes; therefore 53·01 per cent. had been absorbed.

The colour of the fæces was greyish-green to greyish-white, but gave a distinct urobilin reaction, due to the leuco-urobilin. Schmidt's test for urobilin is performed by adding a concentrated solution of perchloride of mercury to the fæces, when a bright red colour is developed if urobilin is present. If there is much urobilin, the colour appears within five minutes; if little, in five to fifteen minutes; if very little, in half an hour. The colour deepens for twenty-four hours. More analyses on the above lines are required. Halberkann in a case he studied found a large amount of *indican* in the urine and a reducing Fehling substance, which was not glucose, undetermined. In the stools he found presence of urobilinogen, and they contained a large amount of fat.

The *blood* coagulates slowly, and there is always some reduction of the red cells, which may fall as low as 3,000,000 to 1,000,000 per cubic millimetre. The colour-index is low, and the structure of the cells is normal. The white cells are also reduced to about 6,000 to 2,800 per cubic millimetre. The ratio of white to red is about 1 to 400 in bad cases. A differential count shows an increase in the mononuclears and eosinophiles.

The *urine* requires more investigation, but as far as evidence goes at present it is not abnormal, showing only an increase in indigo blue and urobilin, and at times Cammidge's reaction for pancreatitis.

Schmitter has often noted loss of sexual power.

The buccal, intestinal, and other symptoms may markedly improve, even without treatment, but only to get worse again; and this is repeated time after time.

In due course the patient becomes very emaciated, weak physically, and depressed and irritable mentally. The skin becomes harsh; the mucosæ anæmic, the tongue becomes smooth, glazed, reddish-yellow, and small, and is often furrowed by cracks, indigestion is marked; and the diarrhœa is worse. The patient continues to lose weight, and emaciates rapidly, the skin hanging in loose folds, the abdomen blown out with gas, the liver small and atrophied, the ankles œdematous, while the pulse becomes slow and feeble.

After this has gone on for a long time, the emaciated, worn-out, irritable person dies of an acute attack of diarrhœa or cardiac failure. Sprue is essentially a chronic disease, with remissions, intermissions, and recurrences, but, unless taken seriously in hand, goes steadily from bad to worse.

Some writers distinguish three stages—a first stage, with oral and dyspeptic symptoms; a second stage, with marked intestinal symptoms; and a third stage, with toxæmia, emaciation, and anæmia; while cases are sometimes seen which are atypical—that is to say, where there are the mouth symptoms without the intestinal symptoms, and *vice versa*.

Complications. The complications met with in the course of the disease are:—Acute diarrhœa; dysenteric diarrhœa; hæmorrhage; meteorism; pancreatitis; myalgia; insomnia; helminthiasis, especially ankylostomiasis; impacted fæces; chronic appendicitis; jaundice; diabetes; and pernicious anæmia.

Diagnosis.—The diagnosis of the disease is to be based upon the irregular chronic diarrhœa occurring especially in the morning, and associated with flatulent dyspepsia, causing distension of the abdomen, and the passage of fermenting, abundant, clay-coloured motions. With these symptoms there will be progressive emaciation and anæmia, and when to these the characteristic mouth-lesions occurring in a person living in the tropics are added, it is indeed difficult to imagine any disease with which it could be confounded. Van der Scheer considers that the discovery of fat in the motions is a diagnostic sign before the disease begins; but this condition may also be found in pancreatitis. Low says that the so-called psilosis pigmentosa of Barbados is pellagra. The diseases from which sprue should be distinguished are stomatitis, hill diarrhœa, chronic dysentery, and chronic pancreatitis.

Stomatitis.—All forms of stomatitis are very common in the tropics, and may be accompanied by intestinal symptoms such as diarrhœa. The stools, however, do not show the peculiar characteristics of sprue—viz., the white colour, the frothy appearance, and the copious amount passed in the twenty-four hours.

Thrush.—This is easily diagnosed by examination of the white patches, in which fungi of the genus *Monilia* will be found. It is, however, to be noted that in long-standing cases of sprue, as in all chronic complaints, thrush may develop.

Hill Diarrhœa.—The patient generally gives a history of residence at a high elevation, and the diarrhœa is as a rule present only in the morning, while mouth symptoms are absent. We have, however, seen several patients in whom sprue has developed after repeated attacks of what to all appearance was simply hill diarrhœa.

Chronic Dysentery.—In chronic dysentery there is an absence of the mouth symptoms, while the motions are not whitish in colour, and may contain blood and mucus during the exacerbations. The diarrhœa of dysentery is generally accompanied by griping, while that of sprue is not. In chronic dysentery pain is often felt on pressure over the sigmoid and descending colons. In some cases microscopical and bacteriological examination of the stools for entamœbæ and the Shiga-Kruse bacillus may be necessary to clear the diagnosis.

Though personally we consider sprue and chronic dysentery to be different diseases, still we have seen several cases of sprue developing in old-standing cases of chronic dysentery.

Chronic Pancreatitis.—Absence of the mouth symptoms of sprue and presence of tenderness in the region of the epigastrium and the passage of large quantities of fat in the motions, together with Cammidge's crystals in the urine, will enable the diagnosis of chronic pancreatitis to be made.

Prognosis.—The prognosis in any case of sprue is serious, because, unless the patient will honestly co-operate with the doctor, he will go from bad to worse. We are of the opinion that, no matter how mild the case may be, the patient should be warned of the danger.

If treatment is properly carried out, the prognosis improves considerably, but even then relapses are apt to occur.

Treatment.—The treatment is symptomatic.

An attempt must be made to soothe the alimentary canal, and to give it as little work to do as possible, so that it may repair itself. This line of treatment will necessitate rest in bed and a careful diet, after the bowels have been swept as clear as possible of decomposing material.

While this is proceeding, care must be taken to avoid chills, as they aggravate the disease. Lastly, an attempt should be made to treat those symptoms which worry and annoy the patient.

The treatment, therefore, may be classified into:—

1. The co-operation of the patient.
2. Rest in bed.
3. Suitable clothing.
4. Removal of fermenting bowel contents.
5. Diet.
6. Medical treatment.
7. Change of climate.

1. THE CO-OPERATION OF THE PATIENT.—The nature of the complaint and the dangers which the patient runs must be carefully explained to him, and the line of treatment sketched out. Further, he must be told that its success or failure largely lies in his own hands. If he has not the strength of will to persevere, even when at first success seems far from certain, he might as well not begin.

If he agrees to co-operate, then he must be carefully weighed, and a chart kept of his weights.

2. REST IN BED.—The second point is that the patient must remain in bed for a little time, and use the bed-pan and the urine-bottle, in order to give the bowels as much rest as possible, and warm water must be used in sponging.

3. SUITABLE CLOTHING.—The underclothes and pyjamas should be of wool or flannel, in order to avoid chills.

4. REMOVAL OF FERMENTING BOWEL CONTENTS.—The treatment should begin with a dose of castor oil, to remove the fermenting contents of the bowel.

5. DIET.—The various diets advised may be arranged as follows:—

(*a*) The milk diet.
(*b*) The milk and fruit diet.
(*c*) The fruit diet.
(*d*) The meat diet.
(*e*) The meat and milk diet.

(*a*) *Milk Diet.*—The real basis of the treatment of sprue at present is the milk diet.

In the tropics, this milk should be obtained from a cow kept for the purpose or from some really reliable dairy, as the danger of contamination is great. Even when the cow belongs to the patient, great care has to be taken that the milk is not adulterated by the household servants. We can never forget that once the milk of a peculiarly careful household, collected, apparently, under strict precautions, was found on analysis to be grossly adulterated.

The lesson we have drawn from the above is to get a sample analyzed from time to time. This analysis costs but little, and the possibility of its being carried out at any time puts a certain amount of restraint upon would-be adulterators.

There is a considerable difference between the average composition of the milk supplied by *Bos taurus*, the straight-backed cow, and *B. indicus*, the hump-backed cow, which, in general terms, may be summarized by saying that the milk of the latter is much richer than that of the former. We have investigated this point, and are of the opinion that if 3 per cent. of fat is considered to be an average for *B. taurus*, then 5 per cent. should be reckoned for *B. indicus*.

In placing a patient upon a milk diet, the composition of the milk should be carefully considered, especially as regards the fat, for, as Harley and Goodbody have shown, no less than 47 per cent. of the milk-fat is passed out in the fæces.

Milk with high percentages of fat should, therefore, be diluted with whey, when the amount of nitrogen will be kept up, while the percentage of fat is diminished. Whey is easily made in the tropics by means of the juice of limes.

Preferably the milk should not be boiled or sterilized, but boiling, apparently, does not interfere with its beneficial properties, and, therefore, if desired or thought necessary—*i.e.*, owing to the risk of typhoid—there is no harm in so doing. In cold weather it should be warmed before being taken. It can be aerated in a seltzogene if desired, and can be mixed with Vichy water. Finally, it must be remembered that milk is not a perfect food for an adult, however suitable it may be for a child.

It is as well to begin with a small quantity, and gradually to increase the amount. Every medical man sooner or later adopts his own method of carrying this out, and we will, therefore, only give general directions. If the case is very severe, with vomiting and much diarrhœa, it is as well to begin with whey only, which the patient should sip slowly, and practically *ad libitum*—*i.e.*, about 7 to 8 pints per diem. As soon as the urgent symptoms are relieved, milk must be added to the diet, as whey alone is starvation.

If the case is of moderate severity, milk can be begun at once, 3 pints per diem being given in the more severe, and 4 pints in the less severe cases—*i.e.*, 60 to 80 ounces—which should be divided into not less than ten meals at regular intervals during the day. The milk must be slowly sipped or taken through a glass tube, which, of course, should be carefully boiled after each meal. On no account must the patient be allowed to drink the milk in gulps. It is, perhaps, as well to define a limit of time—say about twenty minutes—as the minimum time for a meal.

If the symptoms improve, it is necessary to increase the milk gradually every few days until 6 to 7 pints—*i.e.*, 120 to 140 ounces—are given: but in doing this, it is better to increase the number of meals rather than the quantity at a given meal. Twelve meals in the twenty-four hours are not difficult to arrange.

If the symptoms do not improve, the milk must be reduced gradually, or whey must be tried; but as soon as the urgent symptoms of diarrhœa and vomiting abate, the milk must be gradually increased, and, indeed, the starvation must not be long continued in any case. Starvation diets are dangerous in severe cases, when the patients are emaciated and weak; and hence, while they are being employed, great care is required in nursing.

If the milk is succeeding, the diarrhœa ceases, the mouth troubles diminish, and the patient feels better. The fæces will at first be pale and grey, but, as improvement continues, stercobilin will appear, as evinced by the brown colour. This change in the colour of the fæces is a most important sign.

But even if milk is agreeing with the patient, there will be much trouble, as there is often strong objection to milk only. Another difficulty is constipation, and this must be relieved by enemata. Sometimes the milk does not agree, causing vomiting and pain. Usually this can be relieved by alkalinizing the milk with bicarbonate, 1 grain to the ounce, or the citrate of soda, 2 grains to the ounce of milk (convenient tabloids of this salt are prepared by Burroughs Wellcome and Co.), or by adding Apollinaris or Ems water in the proportion of equal parts, or lime-water, 1 to 6 of milk. As soon as a definite improvement appears, and the weight begins to increase, the patient should be allowed to sit up, but great care must be taken to avoid chills. Milk diet should be persisted in for a month or six weeks, but may be modified by the addition of fruit —*e.g.*, strawberries, bananas, or apples—as will be described later.

Then eggs may be beaten up in the milk: chicken-broth can be tried: then Benger's food, or some other simple food—Allen and Hanbury's, Mellin's, Albany food, Carnrick's soluble food, Sanatogen, or Plasmon. Then fish, chicken, or sweetbreads, with a biscuit, and, later, potatoes; and finally, the patient is put on to a diet of eggs, toast, dilute China tea, soups, white meats, custard-puddings, milk. But he must avoid dark meats, most vegetables, spiced foods, iced drinks, and all indigestible substances. Alcoholic drinks in every form are bad, both during the illness and afterwards. Nor is smoking to be encouraged: we, personally, are much against it.

But, unfortunately, a case of sprue is not so easy to treat as indicated above, for, while the food is being gradually and carefully increased, relapses are not infrequent, and a return to milk may be necessitated. The patient gets weary, and at times exceedingly angry about this dieting, and, indeed, is apt surreptitiously to kick over the traces, with disastrous results. The prohibition of alcohol also leads to trouble, but our experience about this is quite clear: if alcohol is taken, the progress of the patient is seriously hindered.

Before leaving the milk diet, two points ought to be mentioned, concerning one of which we have had considerable experience; concerning the other, none at all. First of all, there can be no reasonable doubt as to the advantages of liver soup—*i.e.*, soup prepared from calves' or sheep's livers—in the milder cases of sprue, or in the return to ordinary food of a severe case. The liver treatment is really an old native remedy in Ceylon. We do not profess to advance views as to its action, but in a certain class of cases it is of benefit. Secondly, gall-pills or inspissated bile, as suggested by C. J. Martin, and pancreatic preparations have been advocated by some: but of these we have no experience.

(*b*) *Milk and Fruit Diet.*—A milk and fruit diet has been found to be even better than a pure milk diet in many cases. The milk is administered as already described, but, in addition, fruit is given. Strawberries are most highly recommended, beginning with ¾ pound and gradually increasing to 2½ pounds per diem. They should be crushed, and eaten with sugar and cream. In lieu of strawberries, bananas (not plantains, though people often call bananas plantains, the difference being that a banana shows three cells on transverse section and a plantain five), pears, grapes, in the same weight as the strawberries or apples, from ½ pound to 1½ pounds per diem. If these cannot be obtained, the juice of oranges, papaya (1½ pounds per diem), avocado pears, mangosteens, and sapodilla, may be used.

Fresh Bael fruit is excellent, but must be carefully prepared. It may be boiled in water and then cut open and shredded by means of a fork into warm milk, in which it is pounded with castor-sugar, and finally strained through a fine strainer to remove all débris. This should be used three times a day. Preserved fruit is said to be useful, if fresh fruit cannot be obtained. Acid fruits, such as pineapples and sour-sops, should be avoided, and, personally, we do not advise the use of mangoes.

(*c*) *Fruit Diet.*—This was first advocated by Van der Burg, and usually consists of grapes and pears; but it appears as though almost any fruit which is not acid might be used.

(*d*) *Meat Diet.*—If the milk or fruit diets fail, it is advisable to try a meat diet, or this may be made the basis of treatment from the beginning. Cantlie is the great supporter of this dietary.

If the patient is very ill, it may be necessary to begin with raw-meat juice prepared by pounding sufficient good raw flesh in a mortar, so that, with the addition of 2 ounces of water and 20 minims of dilute hydrochloric acid, 6 ounces of meat-juice is obtained on straining. The quantity of meat required to obtain these 6 ounces will sometimes be quite considerable, and, as it varies in different regions, must be obtained by preliminary experiment. A little salt should be added to this juice, and 1 teaspoonful should be given every quarter of an hour in very bad cases, and rapidly increased in amount if successful.

As soon as the very serious symptoms subside, the meat diet should be started. Brown gives the following directions for preparing a meat diet: Take 2 pounds of good raw meat, free from fibrous matter, fat, and gristle, and 2 ounces of fresh suet, and mince and pound them up thoroughly. Sprinkle the pounded mass with a little salt, and divide into six portions. One portion, cooked in a small, well-buttered saucepan until the red colour has just disappeared, is given six times a day, as convenient. This portion, when cooked, is estimated as weighing 4 ounces. In addition, ½ pint of plain warm water, rice or toast water, is sipped half an hour before a meat meal, and a little tea, with lemon-juice instead of milk, taken twice daily. It may, perhaps, be as well to remind the reader that rice-water is an infusion of roasted rice.

In about a week this meat diet should be changed to a modified meat diet, which is first produced by the addition of fruit, followed in a little time by chicken, then and gradually by eggs, biscuits, and fish, until the dietary already mentioned under Milk is reached.

With a modified meat diet some people combine curdled milk. This is based upon Metchnikoff's researches, which showed that if the *Bacillus acidi lactici* is taken with milk, it generates large quantities of lactic acid in the intestines, particularly in the large bowel, and that this acid interferes with intestinal toxins. Various preparations of the germ have been placed on the market, including 'Sauerin' made by Messrs. Allen and Hanbury, and said to be a pure culture of the germ. Brown gives the following directions for its use: 2 pints of milk are heated to 100° F., to kill off any bacteria which might happen to be present, and then are allowed to cool in a jug which has been boiled. When 100° F. is reached, 6 tablets of Sauerin are added, and 2 tablespoonfuls of sugar, when the milk is curdled in about three hours. This curdled milk is taken four times a day, between the meals of a modified meat diet, and is said to be efficacious.

It may be mentioned that curdled buffalo-milk is commonly used by the natives of Ceylon as a part of their food, and curdled milk is also used in India, and, indeed, in many other places by natives

Under the heading of Meat Diets must be placed Cantlie's treatment, which consists of putting the patient to bed, applying a hot wet pack from the nipples to the groin for two hours, morning and evening, and giving three meals of 5 ounces of meat per diem, and, in addition, either beef tea, beef-jelly, calves'-foot jelly, or a plain jelly every two hours. Castor oil is administered in 1½-drachm doses every morning for the first three days, and santonin in 3-grain doses morning and evening for three days. Strawberries, to the quantity of 3 to 4 pounds per diem, are also allowed between meals. When the stools become solid, and show brown colouring matter, a poached egg and pounded chicken are added, and, later, minced chicken, and, still later, the undercut of meat, with stewed celery, seakale, vegetable marrow, pulled bread, and thin slices of bread, baked in an oven for twenty minutes.

(*c*) *Meat and Milk Diet* Cantlie now advocates that when a patient is on a meat diet, this should be stopped every third or fourth day for twenty-four hours, and that milk only be given during this period.

6. MEDICAL TREATMENT. It may be said at once that astringents as a rule are dangerous, and that antiseptics are not useful.

Santonin, which must be yellow, has been strongly recommended by Begg, who gives 5 grains night and morning in salad oil, but we have seen no benefit by this treatment. Mixtures containing bicarbonate of soda are often useful.

People complain that yellow santonin cannot be obtained, but it can be easily prepared from white santonin by exposure to the sun for a few days. The crystals are turned from time to time until yellow throughout, as demonstrated by crushing. The chromosantonin of Monte-Martini is not santonin, which, according to Lestini, is changed into formic acid and photosantonin acid and a red resinous substance Peter Sys's remedy, which is much used in China, is simply powdered cuttle-fish bone.

Cantlie has had good results by the administration of 20 grains of ipecacuanha daily for two or three days in advanced cases, and emetin has been administered by several authors. Schmidt has used oxygen introduced *per rectum*, ½ to 1 litre weekly.

Castellani has obtained in some cases a remarkable improvement by giving massive doses of bicarbonate of soda.

The mouth may be treated with any appropriate mouth-wash—*e.g.*, glyco-thymoline, glycerine and borax, diluted liquor aluminis, etc. The teeth require attention, and, if there is any pyorrhœa, this should at once be treated by syringing or spraying between the teeth with peroxide of hydrogen solution. Pain may be relieved by painting the raw surfaces with 1 to 5 per cent. solution of cocaine, novocain, alypin, or stovain. The pain along the œsophagus requires morphia. Janowski recommends 5 to 10 drops of a solution of 1 in 1,000 adrenalin, which, he says, gives prompt and permanent relief for œsophagitis. The muscular pains may be relieved by massage, or by pilocarpine nitrate, given in $\frac{1}{10}$ to $\frac{1}{8}$ grain doses three times a day. Intestinal pain may be relieved by hot packs, as recommended by Cantlie. Acute diarrhœa must be checked by a dose of liquor opii sedativus or lead and opium pills. Dysenteric symptoms must be treated as described under Dysentery.

7. CHANGE OF CLIMATE.—It is obvious that, if possible, the patient should be transferred from the tropics to the temperate zone, but only if he is strong enough to travel. There is no advantage in putting him on board a ship in such a condition that he will probably die when changing from the warm to cooler weather. Personally, we are not in favour of a patient being sent from the low country to the hills. If he is able to travel, let him go to the temperate zone.

VACCINE TREATMENT. —Vaccines have been prepared with various bacteria from the mouth, and Rogers and Nicholls report very encouraging results by the use of streptococcal vaccines prepared with streptococci isolated from the mouth lesions. Monilia vaccines have been used by Ashford, Michel, Taylor, and others, who claim satisfactory results.

Prophylaxis.—Nothing of any practical value can be said under this heading.

PSEUDO-SPRUE.

One of us has called attention to some cases presenting clinical symptoms closely allied to sprue and due to bacilli of the Flexner group. Such cases have no dysenteric symptoms, but present the white frothy motions, the sore tongue, and the anæmia as found in typical sprue, but in contrast to this disease they may recover without any change from the tropics, and a vaccine treatment is very useful.

Motility.	*Litmus Milk.*	*Lactose.*	*Saccharose.*	*Dulcite.*	*Mannite.*	*Glucose.*	*Maltose.*	*Dextrin.*	*Raffinose.*	*Arabinose.*	*Adonite.*	*Inulin.*	*Sorbite.*	*Galactose.*	*Lævulose.*
o	A	o	o	o	A	A	A	A	A	A	o	o	o	A	A

Si	*Amygdalin.*	*Isodulcite.*	*Erythrite.*	*Glycerine.*	*Indol.*	*Voges-Prosk.*	*Redn. Nitrates.*	*Neutral Red.*	*Gram.*	*Gelatine.*	*Serum.*	*Broth.*	*Pept. Water.*
	o	A	o	As*	+s	o	o	o	o	o	o	G.T.	G.T

Abbreviations.—A, acid; G.T., general turbidity; s, slight; o, negative result—viz., neither acid nor gas in sugar media, non-motile, non-liquefaction of gelatine or serum, as the case may be.

*** Certain strains are distinctly acid on ninth day.**

The Flexner-like bacillus found in these cases is identical with the typical Flexner, but for the fact that litmus milk was rendered permanently acid instead of the medium becoming first acid and then alkaline. Minor differences with regard to some sugar broths may occasionally also be noted.

HILL DIARRHŒA.

Definition.—Hill diarrhœa is a gastro-intestinal catarrh of unknown cause, occurring mostly at high altitudes in tropical regions, and characterized by the passage of several liquid, frothy, light-coloured motions in the early morning.

History.—Hill diarrhœa was first described by Grant in 1854, in the same paper as that in which he dealt with sprue and dysentery, and later as a disease quite distinct from sprue by Crombie in 1892. The latter writer held that it was liable to occur at an elevation of 6,000 or more feet in India, Europe, and elsewhere. In India he believed the monsoon to be a potent factor, associated, probably, with a diminished barometric pressure. We have seen cases in Ceylon occurring at a much less elevation—for example, at about 3,000 to 4,000 feet.

More recently Duncan has put forward the view that mica in the water is the causative agent. This mica is found in the laterite—*i.e.*, weathered gneiss—which is a common geological formation in the tropics. Singer considers that he has met this disease in four out of six Europeans on an expedition to Abyssinia, when they reached a height of about 5,000 feet.

Ætiology.—The causation of the disease is quite unknown. The theories are:—Diminished atmospheric pressure, the irritation of mica, fæcal contamination of the water, and exposure to cold.

Pathology.—Very little can be said under this heading, except to invite attention to what has already been written under the heading of Sprue with regard to the formation of leuco-urobilin, and to point out that it is obviously to the formation of this body, and not to anything wrong with the liver, that the colour of the motion is due. The morbid anatomy would appear to be totally different from that of sprue, and to be a congestion of the mucosæ of the stomach and bowels, with a proliferation of the mucosal lymph and fibrous tissue in chronic cases. On the surface of the mucous membrane of the small and large bowels there is a thick layer of mucus, but no ulceration.

Symptomatology.—The disease generally begins soon after the patient has arrived in the hills from the plains.

The onset is sudden, beginning with abdominal pain in the early hours of the morning, with the passage of large, frothy, greyish or whitish motions, which produce a sense of relief. The patient goes about his work, but in the early hours of the next morning the symptoms are repeated, and he will complain that his stomach feels blown out, and that he can hear gurgles, and this goes on morning after morning.

If now the patient leaves the hills and comes down to the plains to consult a doctor, he is astonished to find that he is quite well. and perhaps goes back to the hills without having obtained the medical advice which he desired. A relapse takes place, for which he does not as a rule seek advice, as he considers it a trivial complaint, until later he begins to feel dyspeptic, disinclined for his food or work, and now he will seek treatment, notwithstanding the fact that he feels better on returning to the plains. The disease may become chronic, and rarely may lead to a fatal result.

Sequela.—It is said that neglected hill diarrhœa may develop into sprue.

Diagnosis.—The history of the case and the absence of mouth symptoms are sufficient to enable the diagnosis as a rule to be made from sprue.

Prognosis.—The prognosis is good, as recovery is generally quick under suitable treatment, but in certain cases it is found necessary to abandon residence at high elevations.

Treatment.—The treatment is simple and effective. It consists in rest in bed, warm clothing, and ½ to 1 drachm of liquor hydrargyri perchloridi, given fifteen minutes before each meal, and 12 to 15 grains of pepsin, ingluvin, or lactopeptin two hours after the meal. The diet is to be milk, which may be diluted as advised in the treatment of sprue.

Prophylaxis.—Persons liable to the disease should avoid the hills, especially in the monsoon season, and if compelled to go to high altitudes should do so by easy stages.

LOW-COUNTRY MORNING DIARRHŒA.

This affection, described by Castellani, is common in Ceylon, and somewhat resembles hill diarrhœa, but is found in the plains.

Symptomatology.—The patient wakes up about 3 to 4 a.m. with an urgent call to evacuate the bowels, but there is no abdominal pain or straining. After an interval of one to two hours the bowels are again evacuated, and perhaps again two or three more times in the course of the morning. The motions are liquid, generally yellowish or brownish, and do not contain blood or mucus. The condition lasts as a rule for months, but usually ceases on a change of climate.

Treatment.—A dose of tannalbin (gr. xv.-xxx.) or bismuth subnitrate (gr. xv.-xxx.) may be given at bedtime as a palliative.

FLAGELLATE DIARRHŒA.

Definition.—Flagellate diarrhœa is an acute or chronic diarrhœa due to infections of the intestine with *Oicomonas hominis* (Davaine, 1854), *Chilomastix mesnili* (Wenyon, 1910), *Giardia intestinalis* (Lambl, 1859), and *Enteromonas hominis* da Fonseca, 1915, and other flagellates.

History.—From the days of Davaine, observers have from time to time drawn attention to cases of diarrhœa or enteritis thought to be caused by these parasites—*e.g.*, Roos, Epstein, Castellani, Nattan-Larrier, Brumpt, da Fonseca, Chalmers and Pekkola, Escomel, Paranhos, etc.

On the other hand, of late years a number of observers—*e.g.*, Wenyon and O'Connor—do not believe in the pathogenic action of these germs. It is quite true that flagellates may be aerial contaminations of fæces, and that others may perhaps be non-pathogenic. Still, in our opinion, when these parasites are very numerous there can be no doubt that they can and do cause irritation of the bowel and diarrhœa. It is equally true that they can live in considerable numbers in man's intestine without causing diarrhœa, but such a person, in our belief, is a carrier.

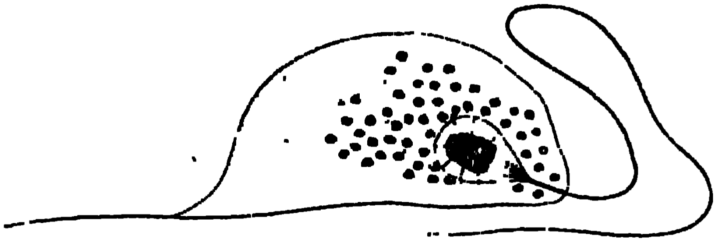

FIG. 759.—*Cercomonas longicauda* DAVAINE.

(After Wenyon and O'Connor, from the publications of the Wellcome Bureau of Scientific Research.)

Climatology.—The flagellates and their associated diarrhœas are to be found in temperate and tropical climes. They are common in Ceylon, the Anglo-Egyptian Sudan, the Balkans, and Brazil, but have been reported from many parts of Africa, Asia, and America.

Ætiology.—It is difficult to prove that the flagellate is the cause of the diarrhœa, but if one of these organisms is present in very large numbers in a case, if bacteriological research fails to demonstrate any pathogenic bacteria, and no other cause can be found, it may be provisionally admitted that they are causal. If the causal organism is killed off and the diarrhœa ceases *pari passu* with this process, and does not return, and the flagellate is either absent or only present in small numbers, the first assumption receives support, but beyond this we cannot at present go.

The difficulty is that the numbers of the parasites wax and wane in the carrier without producing symptoms, but when present in large numbers they are generally associated with diarrhœa. Infection may be by the cysts passing into the alimentary canal of flies, and so to human food, but perhaps it may take place more directly at times. We have never seen them cause true dysenteric symptoms.

From certain experiments carried out by Miss Porter, it would seem that cockroaches may play a rôle as transmitters of flagellate diarrhœas of man. This observer succeeded in transmitting Giardia, Trichomonas and Chilomastix of human origin to clean white rats by allowing their food to be contaminated with the excrement of cockroaches (*Periplaneta americana* and *P. orientalis*) which had fed on infected stools.

FIG. 759A.—CYST OF *Giardia intestinalis* IN FRESH CONDITION IN HUMAN FÆCES.

(Photomicrograph, × 70 diameters.)

Symptomatology.—When in small numbers there may be no symptoms, or the only symptoms are those of diarrhœa, with liquid brown motions, containing yellow flakes, which are composed of epithelial cells and leucocytes, around which the parasites are formed in large numbers.

Treatment.—This is not very satisfactory. It is easy in most cases to stop the diarrhœa by giving a small dose of castor oil followed after some hours by the administration of astringents such as tannalbin and salol in large doses, but it is most difficult to obtain a complete disappearance of the parasites. Methylene blue acts fairly well on flagellates of the genera Cercomonas, Oicomonas, Trichomonas and Chilomastix, but has practically no action on Giardia (Lamblia). It is given in 1 or 2 grain doses twice daily in cachets or gelatine capsules, and in addition enemata of 3 pints of 1 in 3,000 solution of methylene blue may be given twice daily. The patient should be told that the urine will become blue, otherwise he will be much alarmed.

Another method of treatment is to administer calomel at night, a saline purgative in the morning, and during the day powders or cachets of salol combined with bicarbonate of soda. This is done for several days, while the patients are kept on a restricted diet and the motions carefully examined daily for the flagellate. Iodine solution (1 : 1,000) by rectal injection has been recommended by Escomel, but is painful.

Thymol, turpentine, etc., have also been recommended, but these various methods of treatment do not induce a complete disappearance of Lamblia infections.

Prophylaxis.—This consists in preventing flies and cockroaches from access to food by keeping kitchens and outhouses, and all the immediate surroundings of a house, in a good sanitary condition. Kitchens may be wire-netted and fly-traps may be provided both inside the kitchen and outside. Balfour says that 'chicken entrails' are the best baits for large fly-traps situate in the open air The flies may be killed after being caught by means of a daisy killer or any other smoke apparatus.

All fly-breeding places should be destroyed by the removal of the dirt and the digging up and disinfection of the ground.

FIG. 760.—SERBIAN SOLDIER SUFFERING FROM THE EFFECT OF FAMINE DIARRHŒA AFTER THE ALBANIAN RETREAT.

FAMINE DIARRHŒA.

Historical and Geographical.—This condition has been observed in India during periods of famine, and recently by us in the Balkans, in Serbian and Montenegrin troops after the retreat through Albania.

Ætiology.—Bad, insufficient food and extreme fatigue play a very important rôle in the causation. No specific germ has been found.

Symptomatology.—The patient is extremely weak and terribly wasted, though the abdomen may at times be prominent and distended. He may feel famished, but when given food can take very little of it, and cannot digest it. He complains of slight abdominal pains and has diarrhœa; the motions may not be very numerous; they are liquid, of fæcaloid or at times greenish colour, with some mucus, but no blood. The condition lasts usually between a couple of weeks and one to two months, and often terminates fatally.

Diagnosis.—This is based on the history of starvation and extreme fatigue, with diarrhœa without blood, while the patient wastes horribly in a short time, and there are no signs of tuberculosis. It may be differentiated from dysentery by the stools not containing blood, and by the absence of dysenteric germs; from cholera by the longer course and absence of cholera and para-cholera germs.

Prognosis.—This is serious, many cases terminating fatally.

Treatment.—This is very unsatisfactory. Astringents such as bismuth subnitrate, etc., even when given in massive doses, may not stop the diarrhœa; at times they may check it, but the patient continues to become weaker and weaker, and often dies.

CŒLIAC DISEASE.

Gee described in England, in 1888, an infantile affection characterized by its long course, anæmia, great wasting, and pale greyish abundant stools. Cases are not very rare in Great Britain, and have been reported also from other countries. The ætiology is unknown, though various germs have been found. In three cases Nabarro has carried out a very complete investigation, and has isolated from the fæces a dysenteric bacillus of the Flexner type. This result would suggest that the condition might perhaps be ætiologically related to the so-called pseudo sprue of the tropics, described by one of us.

In cœliac disease the tongue apparently does not become affected, and this and also the fact that it is found in children rather than in adults differentiates the malady from tropical sprue.

The treatment consists in very careful dieting. Fresh cow milk should be prohibited, and dried milk given instead, using one of the preparations on the market which contain only a very low proportion of fat. Condensed milk may also be used, but is generally less successful than dried milk. A fruit diet, in contrast to what one sees in true sprue, is badly tolerated, and should never be ordered. As regards drugs, Still's mixture is often found useful:

Ol. ricini	♏v.
Salol	gr. 1½.
Spir. chlorof.	♏i.
Muc. acaciæ	♏xv.
Aq. anethi	ad ℥i.

Ter die.

Occasionally silver nitrate is valuable when the diarrhœa is very marked, and Still recommends it to be given thus:—

Arg. nitratis	gr. ⅛.
Glycerini	♏v.
Aq. dest.	ad ℥i.

Ter die.

Bismuth preparations are practically useless, but tannalbin has at times a favourable action.

CHAPTER LXXVII

THE CHOLERAS

Cholera —Synonyms—Definition—History, Geography, and Epidemiology—Ætiology—Pathology—Symptomatology—Diagnosis—Prognosis—Treatment—Prophylaxis—*Paracholera*—*Pseudocholera*—References.

CHOLERA.

Synonyms.—Cholera Asiatica. *Hindustani:* Haiza. *Tamil:* Enerum Vandec. *Chinese*. Ho-louan. *Arabic:* Duba.

Definition.—Cholera is an acute specific endemic or epidemic disease caused by *Vibrio choleræ* Koch, 1883, and characterized by violent purging, vomiting, muscular cramps, suppression of urine, and collapse.

Remarks.—There is little doubt that in the past the term 'cholera'—in analogy to other diseases—has been used to cover a group of clinically similar affections caused by closely allied germs. See remarks on paracholera, p. 1819.

History, Geography, and Epidemiology.—Cholera appears to have been known in India from the most ancient times, for Charaka and Susruta describe symptoms which most probably refer to this disease. The name is of Greek origin, being perhaps derived from χολέρα, a spout, which may have been applied with the idea that the violent purging resembled the water rushing out of a spout. Apart from the two authors mentioned above, the earliest record of the disease is found in 1438, when Ahmed Shah's army is said to have been decimated by it. After this date there are several references, for it is mentioned by Vasco da Gama in 1490; an account is given of an outbreak in Goa in 1543, another in Pondicherry in 1768, and another in Calcutta in 1781-82, the last of which appears to have spread to Madras, Ceylon, and Burma in 1782-83. Outbreaks occurred in Travancore in 1792, and in the Mahratta country in 1794. But these are only a few of the recorded outbreaks, for, according to Macnamara, no less than sixty-six separate observers mention the disease between the years 1438 and 1817.

With regard to Europe, cholera was recorded at Nismes in 1564, but it and the sporadic outbursts in the seventeenth century may not have been true cholera. It also appears to have been endemic in Java as far back as 1629, and occurs yearly in Southern China and the Philippine Islands.

In 1817 began an epidemic which may have originated in Calcutta or in Jessore, and which lasted till 1823. During this time it spread to the west coast of India, Arabia, Ceylon, Burma, Malacca, Penang, Singapore, and Manilla, reaching Mauritius in 1819 and China in 1820. This is certainly the first extensive epidemic ever recorded outside India. In 1826 the first pandemic, which lasted till 1837, and spread into Europe, Africa, and America, began in India, through which it spread slowly, and then passed to Europe and Africa by three routes, the first and earliest via Kabul, Bokhara, and Khiva to the Russian province of Orenburg, which was reached in 1829. The second route was through Persia, Tabriz, and Tiflis, to Astrakhan in 1830. In this year the two routes met at Nijni-Novgorod, where there is an annual peasant gathering. These peasants, on returning home, infected Moscow, and as there were military operations proceeding in Poland, the disease rapidly spread through Western Russia into Poland, and on to Germany, Austria, Sweden, and England. In 1831 France became infected, and from 1832-33 the whole of Europe was ravaged, and the disease spread to the United States, Mexico, Cuba, and Guiana, and even to Australia. In the meanwhile the epidemic had spread by the third route from Bombay to Arabia in 1826, and then to Syria, Turkey, Egypt, and finally to North Africa in 1834, after which it died down.

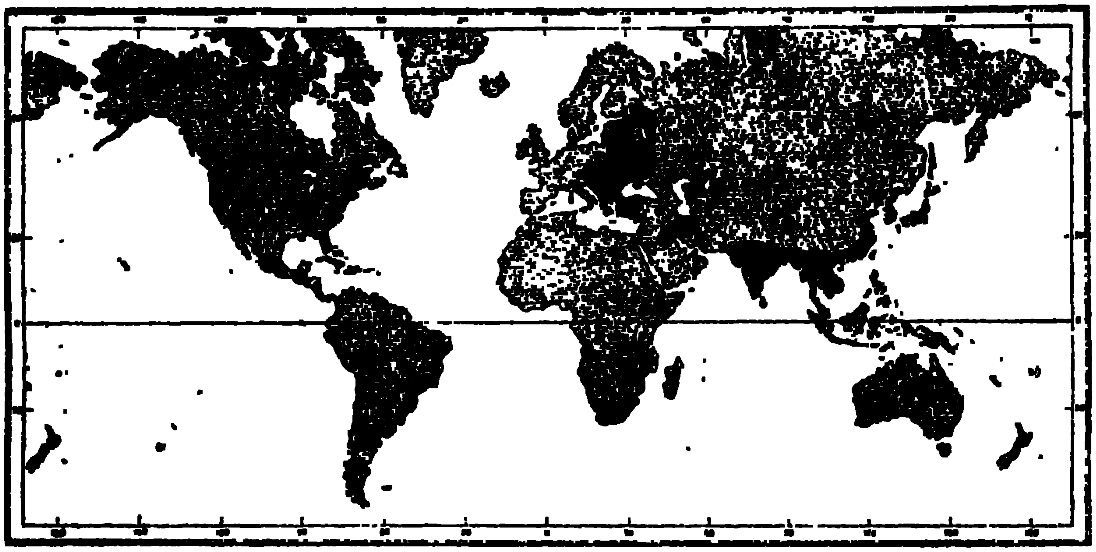

FIG. 761.—DISTRIBUTION OF CHOLERA IN 1915.

In 1840 troops were collected together in India for service in China, and as they travelled eastwards they carried the cholera, which was present in Bengal and Madras, to Malacca and China, in which country it was very prevalent in 1841, and through which it spread, reaching Northern Burma in 1842. It now proceeded north of the Himalayas, reaching Yarkand, from whence it passed to Bokhara and Afghanistan, and spread into the Punjaub and the North-West Provinces in 1844, and into Persia in 1845, when it again travelled via Tabriz and Derbend to Orenburg in 1847, and so to Europe and America in 1848. In this year it was very prevalent in India, spreading again from Bombay to Arabia in 1851, and to Turkey in 1853; while it also again travelled via Persia to Russia in 1852, and so over Europe. This epidemic lasted till 1857, and affected the troops engaged in the Crimean War.

The fourth extensive epidemic began in 1863, and spread to Europe by the two usual routes—viz., via Persia and Arabia—and lasted till 1875, extending as usual to America.

The fifth epidemic began in 1879, when the disease passed from Mecca to Egypt, and so to Europe. It was during this epidemic that Koch discovered the *Vibrio choleræ* in Egypt in 1883.

The sixth epidemic (1891-96) appears to owe its origin in India to the great bathing festival at Karagola, on the Ganges, which, being only held once in thirty years, came as a surprise to the officials, who were not prepared for it. Cholera broke out among the pilgrims on February 8, 1891, and spread rapidly, reaching Europe in 1892.

The seventh epidemic began in 1900, and may be said to be continuing at the present time. It started in 1900 in India after a severe famine, and spread extensively through that country, and then began to travel, reaching Japan in 1901; Arabia, Mecca and Jeddah, Egypt and Erythræa, Syria, Persia, and the Philippines in 1902; Palestine, Asia Minor, and Mesopotamia in 1903; Persia, Russia, and Turkey in Asia in 1904; Russia, Germany, and the Philippine Islands in 1905; Russia (few cases), Burma, Siam, Singapore, Japan, China, and the Philippine Islands in 1906; Ceylon, Peshawar, Singapore, Philippines, Japan, Korea, Manchuria, China, Russia, Turkey, and Persia in 1907; China, Russia, Mecca, and Medina in 1908; and Russia in the beginning of 1909. In 1910 it was present in Russia and Italy. In 1911 it was recognized in Turkey, Roumania, Hungary, Austria, Italy, and Russia, and in 1912 in Turkey, Italy, and Russia.

In 1914 the Dutch East Indies were attacked, and during the war the Austrian Army and civil population were attacked, especially in Galicia, as well as Bulgaria and Greece, while Turkey has also suffered. In 1915 Brčka, in Northern Bosnia, was infected.

Some places have always so far escaped the visitation of cholera. These are either situated in the colder regions, of which the climatic conditions are unsuitable for the propagation of the disease, or are islands to which the disease is less likely to be brought, or where precautions are taken. As examples of these islands may be mentioned the Andaman and Pacific Islands, Réunion, the Azores, etc. Tropical and Southern Africa have not yet been infected.

The climatic influences which appear to favour the development of the disease are low-lying areas, and soils easily permeable to water, especially if they are polluted with decomposing matter. It would, however, appear that the most inimical climatic conditions can be overcome if there is lack of cleanliness, especially with regard to drinking-water and food, together with bad sanitation, and the disease may spread where every climatic influence is opposed to it. With regard to the use of permanganate of potash in cholera, it was recommended in 1866 by Everest, who treated seventeen cases with Condy's fluid, with only one death. Dr. Mackie in the same year treated six cases similarly without a death. In 1884 J. W. Fry stated that the only thing he found of remedial use was an enema of diluted Condy's fluid. In 1910 Rogers reported favourably of the use of the permanganates given liberally in cholera. In 1913 Castellani definitely separated the condition which he called paracholera, from cholera.

Ætiology---*The Vibrio.*- The cause of the disease is undoubtedly Koch's vibrio (p. 962); still, this alone may not produce illness, for, as Dunbar showed in 1892 in Hamburg, people who had never suffered from the disease, and who were in good health, might still be passing quantities of the virulent micro-organisms in their fæces. It is evident, therefore, that these persons lacked some predisposing condition, and, further, that they must have been a fruitful source of infection. What this condition may be we do not definitely know, but it would appear that such factors, as mental worry, underfeeding, and any slight disorder, but specially any derangement of the alimentary canal producing diarrhœa, are predisposing causes. With regard to these causes, it may be mentioned that unripe fruit, and especially melons, are regarded with suspicion in times of epidemics, probably because ey cause diarrhœa, and thus predispose to the disease.

It may be that the vibrio merely live in the en of the bowel in the cases in which it causes no symptoms, d only gains access to the epithelial cells and mucosa in cases of wered vitality, and perhaps is only toxic in this situation: but if th is so it still remains to be proved.

This lowered vitality would explain the apparently extraordinary cases which at times appear in gaols when the town is apparently free. The reason may be that short-sentence prisoners are generally on a very low diet, while long-sentence prisoners often have such hard manual labour to perform that they are exhausted at night. Therefore, if a carrier is introduced into a gaol, the disease may easily start apparently *de novo* among incarcerated inmates.

The disease is communicable directly from man to man by contamination. As an example from our own experience, a medical man examines a patient suffering from cholera, and then proceeds to have his lunch, with the result that both patient and doctor were dead within twenty-four hours of cholera. Again, there is the chance of infection from dead bodies in performing autopsies, but graveyards are not important means of dissemination of the disease, because the germ rapidly disappears from the dead body. Fomites may also spread the contamination, but these are not the usual method of infection, which is generally by water. The vibrios pass out with the fæces, in which they are capable of living a long time (163 days); hence the great danger of fæcally contaminated fields, rubbish-heaps, gardens, etc.; for if there is a poor sanitary system in the place, and if fæcal pollution of the drinking-water is possible, the disease may easily become epidemic, for it has been shown that the vibrios can not merely live, but multiply, in water, though the conditions under which they do this are not perfectly understood.

Two classical instances are usually quoted as evidence of the spread of the disease by water. The first of these is the infection in 1854 of a lady and her servant in Hampstead, where there was no cholera, by drinking the water of the Broad Street well, which was infected, the water being carried all the way from Broad Street to Hampstead because the lady in question had a special liking for it. The second is the infection of Hamburg in 1892 from the waters of the Elbe, in which cholera vibrios were found in the river-water and that of the hydrants.

As water is a method of infection, it is quite easy to understand that milk is specially dangerous, for it is often diluted with water, and, moreover, forms an excellent medium in which the germs can grow. Thus Haffkine and Simpson found that an outbreak of cholera in the Gaya Gaol was due to the contamination of the milk, from which they obtained the vibrio.

The Carrier.—Of great importance in the dissemination of the malady are the so-called vibrio-carriers—viz., persons who, though themselves in good health, still harbour the germ in their intestines, or individuals who continue to harbour the germ for months and years after an attack is over.

Greig has demonstrated that carriers can show an increased titre for the agglutination of the vibrio. His researches also show that the vibrio can live for long in the gall-bladder of animals, and he has also demonstrated it in the human gall-bladder.

The fact that the germs can live for a long time in fæcal matter enables them to infect insects such as flies, and perhaps ants. With regard to flies, the germs have been found not merely on the exterior of the body, but also in the alimentary canal, in which they are believed to multiply. The habits of flies make them, therefore, an important possible means of dissemination of the disease.

Barber, in 1914, brought forward experimental evidence showing that the germ could live for a time in the alimentary canals of *Periplaneta americana* (the cockroach) and *Monomorium latinode* Mayr (the red ant).

Fæcal matter may also pollute green vegetables, for in the East vegetable-gardens are often contaminated with human fæcal matter. The most dangerous vegetables are those which are eaten raw, such as lettuces, watercress, and tomatoes. While, however, the above methods explain many points in the epidemiology of cholera, they do not afford a full explanation of the spread of the disease. As we have already said, the principal endemic centre is Lower Bengal, whence it can spread through India, and, indeed, over the greater part of the world, by human agency and along lines of human intercommunication, but in so doing it may miss places on the direct route of its march. The reason of this is not clear. Certainly climatic conditions may be of importance, and perhaps a low level of the subsoil water and a high earth temperature, together with an imperfect sewage disposal and contaminated source of the drinking-water of the place, may have something to do with this anomaly.

Another point which is by no means understood is the fact that the disease remains for years in the endemic region, and then suddenly spreads in epidemic and pandemic form, extending at times over the whole world.

The ætiology may, therefore, be summarized by saying that the disease is caused by Koch's *Vibrio choleræ* acting in the presence of some unknown bodily condition or conditions, and spread directly from man to man by fomites, water, insects, and food, but the reasons for its endemicity and epidemicity are unknown.

When travelling from one place to another, it always adopts channels of human intercommunication, which may be ships, rivers, roads, or railways. When introduced into a locality, it will give rise to a widespread epidemic if the sanitation is so defective that the germs gain access to the drinking-water, but will be far less extensively spread if due to food or insects, and will be merely sporadic if spread from man to man.

Pathology.—The vibrio grows in the lumen, the glands, the epithelial cells, and the mucosa of the small intestine, probably producing an endocellular toxin, which is set free and causes the symptoms.

The question of toxin formation has, however, been much debated. Thus, in 1905, Brau and Denier considered that they had obtained a soluble toxin. In 1906 Kraus said that he had obtained a soluble toxin which caused the disease, and in the same year MacFadyen obtained a virulent endotoxin. In 1907 Strong carefully investigated the subject, and concluded that he was unable to find a soluble toxin as described above, but that MacFadyen's endotoxin was the true toxin which caused the symptoms in man. This endotoxin causes great gastro-intestinal disturbance, leading to the passage of fluid from the blood to the bowel in the following order: First water, and then inorganic salts, especially sodium chloride; later, phosphates and potassium salts; and still later organic substances. This endosmosis causes a great concentration of the blood, producing a high specific gravity, which may reach 1073 to 1078, which is associated with a great increase in the erythrocytes—8,000,000 per cubic millimetre, according to Rogers and Megaw—with a corresponding increase of the hæmoglobin and of the leucocytes, which may number from 14,000 to 60,000 per cubic millimetre. At the same time the alkalinity of the blood is decreased and its coagulative power altered, while the oxygen contained therein is decreased.

The decrease of the alkalinity of the blood may be very marked in severe cases, and Rogers, Sellards and Shaklu give great importance to this so-called cholera acidosis.

The concentration of the blood causes a fall in the blood-pressure, which is indicated by the feeble compressible pulse, but which, to be studied properly, requires investigation by means of a Riva-Rocci's instrument, as has been done by Rogers and Megaw, who found that in typical collapse the blood-pressure might be only 60 to 50 millimetres of mercury, when the patient is markedly cyanosed and restless. If the case is not so serious, the pressure may be higher—70 to 80 millimetres of mercury—and if the patient is on the road to recovery it may reach to 90 millimetres. As a result of this low blood-pressure, the urine may be suppressed or scanty, with a high specific gravity, albumen, casts, and a large quantity of indican.

The body appears to react to the disease by the pouring out of substances from the blood which are probably bactericidal, though Edwards's attempt to prove this failed because of decomposition and the admixture of other micro-organisms. Agglutinins are absent in fatal cases, but, according to Greig, in non-fatal cases they begin to rise after the sixth day, but drop after the twentieth day.

When recovery is about to take place, the specific gravity of the blood decreases, the blood-pressure rises, and the urine becomes abundant. As convalescence continues, the great danger is secondary infection of the body by other micro-organisms, which may cause serious illness and even death.

It is important to note that Greig has found the germ in the gall-bladder (40-70 per cent. of cases)—where it causes cholecystitis, and in animals may give rise to gall-stones—in the lung, kidney, and urine. According to Violle's researches, bile *in vivo* tends, however, to hinder the development of the cholera vibrio. According to the same author a small dose of cholera toxin excites the secretion of bile while a large dose stops it. It is suggested that a septicæmia takes place, but this has not been demonstrated. Manson suggests that it may pass by the lymph channels.

Danysz regards the disease as of anaphylactic origin.

Morbid Anatomy.—Usually post-mortem rigidity is very well marked, and the body keeps warm for some time after death. On cutting into the tissues, it is noticed that they are very dry, and that the blood is often thick and tarry. On opening the peritoneal cavity, the hand experiences a peculiar sticky sensation not felt in any other disease with which we are acquainted.

The stomach is usually empty, and the bowels are reddish in appearance, with injected vessels. When a piece of small bowel is opened, the contents are usually found to be whitish or greyish grumous material; more rarely will the contents be blood-stained. These contents consist of food particles, epithelial cells, red and white corpuscles, and micro-organisms. When allowed to stand, they separate into liquid and solid portions, the former containing albumen, and having a specific gravity varying from 1005 to 1015. The mucosa of the stomach and bowels is hyperæmic and swollen, and may be marked by ecchymoses. There is usually some enlargement of the solitary and agminated glands, as well as of the mesenteric glands.

The liver is generally congested, and the ducts full of bile; the spleen is shrunken; the kidneys are swollen, and often ecchymotic, with tubules blocked with granular débris and cells in a state of cloudy swelling. The right heart is often dilated, and the whole venous system full of blood, while the arterial system and the left heart is empty. The lungs are collapsed, dry, and anæmic, and the brain may be congested.

Microscopically, the vibrios may be seen in Lieberkühn's follicles in the epithelial cells, and in the mucosa of the intestine and the stomach. The kidney shows vascular congestion and destruction of the epithelium. Usually the vibrios do not penetrate into the blood-stream, and therefore the disease is mainly a general intoxication: but Rebowski records cases in which they have been found in the liver, the kidney, and the heart, thus producing a general infection.

If the post mortem is held on a case which has died during the state of reaction, pneumonia and the signs of other secondary infections may be found.

Symptomatology.—A typical case of cholera has an incubation period which varies from a few hours to a few days (three to six). The onset is usually sudden, but there may be prodromata in the form of diarrhœa, or merely a feeling of illness and malaise. The attack begins with diarrhœa, with or without colicky pains in the abdomen. The motions are at first fæculent, and contain bile, but soon assume the typical rice-water appearance, in which they are fluid and acholic, containing numerous white flakes, which, when examined, are found to be composed of mucus containing vibrios and epithelial cells, while exceptionally the motions contain blood. Vomiting generally appears early, food being first expelled, followed later by a watery fluid, with which bile and occasionally blood may be mixed. The patient complains of thirst, and at times of hiccough. As the purging and vomiting proceed the urine diminishes, and may stop, and fluid departs from the subcutaneous tissues, which therefore contract, so that the facies alters, the nose becoming sharp, the cheek-bones prominent, the eyes sunken, and the skin of the fingers becomes wrinkled like that of a washerwoman. Whilst this is taking place, the circulation becomes profoundly affected, the blood-pressure falls, the pulse becomes weak and rapid, the heart-sounds diminish, and the lips, face, and nails become bluish. The patient now has difficulty with his breathing, and his voice becomes weak and husky. Painful cramps appear in various muscles, but especially in the calf, arm, and abdominal muscles, while the reflexes are diminished. The mind is quite clear, but the patient is apathetic, except when agonized by the cramps. The skin feels cold, and the axillary temperature falls below normal, but that of the rectum may be considerably raised. If no change for the better takes place, the patient passes into the algide stage, in which the failure of the circulation becomes more marked, the pulse almost disappearing at the wrist, the heart becoming weak and irregular, the respirations laboured, the skin cold and deeply cyanosed, the urine suppressed, while the diarrhœa may or may not cease, and the temperature falls far below normal. The first heart-sound becomes impure, or a hæmic systolic murmur may be present, and the second may be faint, and friction-sounds may be heard over both the pericardium and pleura. The patient may now become comatose, and death supervenes in from twelve to thirty-six hours after the onset of the attack. If recovery is to take place, the diarrhœa diminishes, the skin becomes warmer, the pulse and blood-pressure improve, and after a time bile appears in the motions, and the skin fills out with fluid again.

Sometimes convalescence is rapid. In some a secondary febrile condition ensues, which may last for several days, or even for a couple of weeks.

The patient may at times pass into a *status typhosus*, with flushed face, raised temperature, dry brown tongue, low muttering delirium, with subsultus and toxic tremblings and toxic rashes, which may be erythematous, papular, or hæmorrhagic. The urine is diminished in quantity, has a high specific gravity, and contains albumen and casts. The motions are somewhat like those of typhoid, or may be bloody.

Death may take place during this stage from complications, or recovery may ensue after a long convalescence. The infection of the convalescent may be said to have ceased when on three separate days the bacteriological examination of the motions is negative.

The typical course of the disease, as described above, is often arbitrarily subdivided into three stages: (1) The stage of evacuation; (2) the algide stage; and (3) the stage of reaction, when the patient is about to recover.

Varieties.—Cholera cases at times present many varied features, which are usually classified into:—

1. *Ambulatory Cases.*—There are cases in which, without any signs of disease, the vibrio may be obtained from the fæces. These people are genuine carriers of the disease.

2. *Choleraic Diarrhœa.*—Choleraic diarrhœa is characterized by severe purgation, associated with the passage of yellowish motions, which contain the specific vibrio. This condition may be recovered from, or may pass into a typical attack of the disease.

3. *Cholerine.*—The patient is suddenly seized with abdominal pains, and passes numerous fæculent motions, followed by typical rice-water motions, which speedily cease, and the patient quickly recovers without further symptoms.

4. *Cholera Gravis.*—This is the typical form already described.

5. *Cholera Sicca.*—In this type the patient becomes rapidly collapsed, and dies before the typical symptoms of diarrhœa and vomiting can appear. The post-mortem and the bacteriological

examination of the bowel contents reveal the true nature of the disorder.

Complications.—In rare cases hyperpyrexia has been noted during the attack, but usually all the complications occur during the stage of reaction, and are due to secondary infections. The most common are pneumonia, enteritis, and inflammation of the kidney. Pregnant women always abort, and the fœtus may show signs of the disease. The reason of this abortive tendency is, according to Schütz, because cholera has a powerful effect upon even the non-pregnant uterus, causing hæmorrhage during the stage characterized by muscular cramps.

Sequelæ.—After such a severe illness, it is usual to find more or less permanent damage to the health of the victim. Thus anæmia, inflammation of the parotid, gangrene, ulceration of the cornea, astigmatism, or other errors of refraction, a tendency to diarrhœa, and digestive disturbances, may persist for a long time.

Diagnosis.—The diagnosis is easy during an epidemic, but it may be very difficult in the period when there are only a few sporadic cases preceding the outbreak.

So closely may cholera be simulated by ptomaine poisoning as regards the collapse, and by infections with germs of the Aertrycke-Gärtner group, which we have seen produce typical rice-water motions, that it is perfectly useless in a sporadic case to attempt to make an accurate diagnosis without a bacteriological examination, and even this has to be performed with the greatest care, as there are many vibrios which are undistinguishable without special tests from the *Vibrio choleræ* Koch. We recommend the following method:—

1. Make films from the rice-like flakes, and stain with diluted Ziehl carbolic fuchsin (1 in 5 for ten minutes, or with Löffler's blue, five minutes. If a large number of curved rods be present, cholera may be suspected: but a definite diagnosis should never be based on the simple microscopical examination, as comma-like germs are found in many cases of ordinary diarrhœa, and even in normal stools.

2. Inoculate four tubes of peptone water with the suspected stools, the first with ¼ c.c., the second with ½ c.c., the third with 1 c.c., and the fourth with 2 c.c.; or inoculate each of two Erlenmeyer flasks, capped with sterile filter-paper without wool-plugs, with 1 c.c. of the stools. The formation of a scum on the surface of the medium within eight to ten hours is suspicious of cholera. The pellicle and the upper portions of the medium should be examined microscopically for the presence of vibrios, and a microscopical agglutination test carried out, mixing one loopful of the culture with one loopful of diluted cholera serum (1 in 1,000). The peptone water should be tested for the presence of indol, adding a few drops of pure sulphuric acid. In true cholera the indol reaction is generally present eight to ten hours after inoculation. From the pellicle and upper portion of the peptone-water tubes ordinary agar and MacConkey agar plates should be made, and any suspicious

colony developing should be further examined and the germ investigated as regards the following characters:—

(*a*) *Motility.*—The cholera vibrio is very actively motile.

(*b*) *Morphology.*—The cholera organism is often bent, comma-like, but may be straight, bacillus-like.

(*c*) *Agglutination.*—A strong anticholera serum obtained from some well-known laboratory should be used. Any vibrio found in stools which is agglutinated by this serum in a dilution not less than 1 in 2,000 can safely be considered, as a rule, to be the true germ of cholera. In doubtful cases, all the cultural characters should be studied, and Pfeiffer's test and Castellani's absorption test should be carried out.

Dunbar has recommended a special agglutinative test, which consists in mixing directly a drop of the stools with diluted immune serum. The cholera vibrios become agglutinated. This process is practicable only when the stools contain many vibrios.

3. Take a rice-like flake, and smear it direct on to the surface of MacConkey's lactose-agar plate, using a sterile bent glass rod or Kruse's platinum pencil. Inoculate with the same rod or pencil without recharging the surface of two more plates, and incubate at 35° C. The colonies of the cholera and cholera-like vibrios develop on MacConkey's medium as delicate, small, yellowish, roundish dots within twelve to eighteen hours. Any suspicious yellowish colony should be examined, and the germ investigated as regards motility, morphology, and agglutination, as already mentioned.

4. Inoculate the surface of three ordinary serum-tubes with the suspected stools, and incubate at 35° C. If within sixteen hours there is no zone of liquefaction in the medium, cholera may be practically excluded. If there is liquefaction, this may be due to the presence of the cholera or other serum liquefying germs, or to the stools containing an amount of proteolytic substances. The liquefied serum may be plated on MacConkey or ordinary agar plates, and any suspicious colony further investigated.

5. Dieudonné's special strongly alkaline blood agar may be used for the isolation of the cholera vibrio in faeces. On this medium the cholera germ grows well, forming pearl-like colonies, while the coli and coli-like organisms scarcely vegetate. Of course, the colonies which grow must be carefully investigated, as already described.

6. *Bandi's Method.*—The suspected faecal matter is inoculated into a sedimentative tube containing peptone water and a certain amount of immune serum. After incubation at 37° C. for three to seven hours this tube shows, if the case is one of cholera, numerous small flocculi, which at first are in suspension, and later sink to the bottom. These flocculi consist of agglutinated vibrios.

7. *Ottolenghi's Method.*—The suspected stools are inoculated in a medium consisting of pure bile mixed with 3 per cent. of a 10 per cent. solution of sodium carbonate, which after incubation at 37° C. for some hours is plated and further investigated.

8. *Aronson's Method.*—This is an alkaline agar medium containing cane sugar and dextrin, with fuchsin and sodium sulphite as indicator. Good results have been recorded by several observers.

9. *Castellani's Method.*—Inoculate peptone water tubes (it is of advantage to use centrifuge tubes) with the fæcal matter in the usual way, but before or immediately after making the inoculation add to each tube 3 to 5 drops polyvalent lactose fermenting fæcal bacteria serum (*B. coli*, *B. pseudo-coli*, *B. coli tropicalis*, etc.), or the respective mono-serums may be used; 3 to 5 drops polyvalent non-lactose fermenting fæcal bacteria serum (*B. proteus* group, etc.); 3 to 5 drops paratyphoid B serum. The addition of the last-named serum is made with the object of agglutinating and delaying the growth of the bacilli of the paratyphoid B and *aertrycke* type, which, in the tropics at least, are not very rarely found in the intestinal fluid. Care should be taken, of course, to use serums containing no coagglutinin for the cholera vibrio, or only in very small amount. Or serums can be used from which the cholera coagglutinin—which is always in very much smaller amount than the other coagglutinins—has been removed by absorption. The tubes are placed in the incubator, and the further steps in the investigation are carried out in exactly the same manner as with the ordinary methods. For details see *British Medical Journal*, October 13, 1917.

A modification of the method consists in inoculating ordinary peptone-water tubes with the fæcal matter, and, after four to six hours, from the upper portions of these tubes inoculations are made in peptone-water tubes containing a few drops of intestinal bacteria polyserums.

If material has to be sent to a central depot for bacteriological examination, certain precautions must be carried out. The fæces must be carefully collected, if possible into a bed-pan which has been scalded or boiled, or a loop of small intestine carefully removed post mortem. These specimens must be forwarded in a glass bottle, which, as well as the cork, has been boiled. It is, perhaps, hardly necessary to state that no antiseptic must be mixed with the specimens.

Prognosis.—The prognosis is usually bad at the beginning of the epidemic, but improves as the epidemic continues. The case-mortality may be stated to be on the average about 50 per cent.

Treatment.—The treatment of cholera must aim at the destruction and removal of the vibrios, the neutralization of the toxins, the prevention of secondary infection through the damaged intestinal mucosa, the healing of which must be assisted, and the relief of symptoms.

To promote these objects, the patient must at once be sent to bed, no matter how slight the attack may seem to be. His room should be airy, and he should not be allowed to leave the horizontal position. The bed-pan and urine bottle must be used, and the former should be slightly warmed.

The best treatment is that devised by Rogers, which is as follows:—

The patient is given as much calcium permanganate water (1 to 6 grains to the pint) as he can drink, and permanganate pills every quarter of an hour for two hours, and then one pill every half hour (any pill rejected by vomiting being immediately replaced). These pills are continued until the stools become green and less copious, which may occur in twelve to twenty-four hours. At the beginning of the second twenty-four hours eight pills are administered within four hours, and in severe cases this is repeated at the beginning of the third twenty-four hours. In mild cases after the first twenty-four hours the pills are only administered every four hours.

The composition of the pills is:—

Potassium permanganate	2 grains.
Kaolin and vaseline as may be required to make a pill.	

This pill is coated with a varnish composed of 1 part of salol and 5 parts of sandarach varnish, or with keratin. Pills kept for any length of time are apt to become hard and useless.

The patient must be kept warm, and supplied with plenty of water to drink, which preferably should be taken in sips, and sinapisms or turpentine stupes should be applied to the abdomen.

When collapse has set in, hot bottles must be applied to the extremities and round the body, and when the pulse fails, the median cephalic vein should be opened at the elbow, and Rogers's special silver cannula, made by Messrs. Down and Company, inserted, and through this injections of hypertonic saline solution should be injected until the blood-pressure returns as tested by the pulse, or more preferably by a Riva-Rocci's instrument. If the blood-pressure sinks below 70 millimetres, Rogers considers this to indicate the presence of a dangerous degree of collapse and an indication for an immediate intravenous injection. He takes the specific gravity of the blood by the simple method of placing a drop of blood in the centre of a small vial containing a mixture of glycerine and water of known specific gravity (at the mean temperature of the air), and if the droplet rises or falls, trying another vial of lesser or greater density until the right specific gravity is reached.

He concludes that, if the specific gravity is over 1060, while the blood-pressure is low, a copious intravenous injection may be safely administered. If the specific gravity is over 1065, even if the blood-pressure is over 70 millimetres, it is advisable to give an intravenous injection, as the blood is dangerously concentrated, and a single evacuation may lead to a rapidly fatal collapse.

Restlessness, cyanosis, and cramps are also taken as indications for intravenous injection, especially if the blood from the pricked finger is black, and may be obviously thicker in consistency than normal.

The hypertonic saline solution recommended by Rogers is:—

Sodium chloride	120 grains (8 grammes).
Calcium chloride	4 ,, (0·25 gramme).
Potassium chloride	6 ,, (0·4 ,,).
Water	To 1 pint (568 c.c.).

The temperature of the sterilized solution (in an emergency pure water filtered through cotton-wool, and boiled for fifteen minutes will suffice) has to be judged by the rectal temperature. If this is 99° F. or over, Rogers injects the fluid at about the normal temperature of the body (98·4° F.)—*i.e.*, the flask temperature is about 100° F. If the rectal temperature is a degree or so below 99° F., the temperature of the solution in the flask should vary from 102° to 104° F. If the rectal temperature is high—*i.e.*, over 100° F.—the solution should be run in below 98·4° F.: if the temperature is over 102° F. the solution should not be warmed. About 4 pints of fluid are required for an adult male, but the case must be carefully watched, and the injection stopped if any distress of increased frequency of respiration is noted. These injections may have to be repeated several times, and therefore the cannula must be left *in situ*. At the same time, hypodermic injections of strychnine, provided there are no severe cramps, with or without atropine, should also be given, and warm rectal injections.

During this treatment the bladder must be carefully watched to see whether urine is being passed or not, and if suppression occurs, dry-cupping should be performed over each loin.

In some cases, especially when anuria has developed, an alkaline solution acts better, and Rogers recommends the following: Sodium chloride, 4 grammes; sodium bicarbonate, 10 grammes; water, 500 c.c. Bayliss' solution (6 per cent. gum acacia in 0·9 per cent. sodium chloride solution) may be used.

When the stage of reaction sets in, a mixture containing salicylate of bismuth gr. xv., bicarbonate of soda gr. v., liquor opii sedativus min. v., mucilage q.s., and chloroform water 1 ounce, should be given, and later one containing alkalis and digitalis is useful.

With regard to symptoms, the persistent vomiting may be relieved by small pieces of ice or by $\frac{1}{4}$ grain of cocaine dissolved in a teaspoonful of water, or by a dose of 10 minims of mistura pepsini composita et bismutho every half-hour until four doses have been given, or by one or two drops of tincture of iodine in water. Cramps are treated by massage, assisted by rubbing with dry powdered ginger, by hypodermic injections of morphia, or by inhalations of a mixture of chloroform and oxygen. Prostration must be combated by hypodermic injections of strychnine or of camphor in ether. Delirium must be relieved by bromides with tincture of hyoscyamus.

The treatment of complications, such as pneumonia, etc., must be conducted on the lines laid down in textbooks on general medicine.

Other methods of treatment may be briefly mentioned. Many disinfectants are recommended by different authors—*e.g.*, a mixture of sulphocarbolates of zinc, 2 grains, soda, 2 grains, calcium, 3 grains, dissolved in peppermint. Acetozone, alphazone, and medical cyllin are recommended by O'Gorman, and both he and Waters advise the administration of 15 minims of medical izal dissolved in 1 ounce of water every two hours. Salol has been strongly recommended by some writers, and Brown and Banerji praise an emulsion of eucalyptus oil with mucilage and syrup of lemons, of which 5 minims are given for a dose. O'Gorman advises copper arsenite for infants, while Duke recommends red iodide of mercury in the algide stage, and Choksy cyanide of mercury in $\frac{1}{16}$-grain doses in syrup and water every two or three hours, but says this is apt to cause stomatitis during convalescence, which can be avoided by regulating the doses. Cantani long ago advised slow intestinal injections of 3 to 4 pints of a 1 per cent. solution of tannin, with or without 20 to 40 drops of tincture of opium, and warmed to 100° F. and given every three to ur hours. Denier's serum treatment has been found useless by Strong, ut Kolle's serum promises to be more useful. Berdnikoff gave 30 to 50 c.c. f Schurupon's serum intravenously and subcutaneously with success. Salim-ni used 100 to 350 c.c. Pasteur Institute serum together with saline ected subcutaneously and intravenously. Macfadyen and Hewlett have

prepared an endotoxic serum, and Violle has prepared a serum by inoculating the cholera vibrio in the gall-bladder of rabbits. Several authors recommend treatment by repeated hypodermic injections of morphia, and others adrenalin and pituitary extract. Kuhne recommends massive doses of bolus alba (kaolin).

With regard to diet, no food should be given during the acute attack, but merely liquids, which should consist of water, iced water, iced soda-water. Stimulants should only be given with great moderation, and carefully by the mouth, as at times they are apt to do more harm than good. In the algide state the liquids given should be warmed, and hot black coffee may be used as a cardiac stimulant.

When reaction sets in, only the mildest foods must be allowed, and then only with care. Begin with thin arrowroot, and continue with milk mixed with soda-water, and then with milk, barley-water, rice-water, etc. Sanatogen, plasmon, and somatose are also recommended. Meat-extracts should be avoided. As improvement continues, the diet may be slowly and carefully increased, but the greatest care must be taken for a long time.

Prophylaxis.—The prophylaxis must be based upon the knowledge that the disease is carried by man, and is spread from one man to another by water, milk, contaminated food, especially green vegetables, and insects, especially flies and perhaps ants.

The methods which may be adopted are classifiable into private and public.

Private Methods.—At the beginning of an epidemic it is as well to circulate a printed notice in English and in the vernacular telling the householder what he should do to prevent the disease attacking his household. It is the duty of the head of every household to personally inspect twice a week at least his kitchen and go-downs, and especially his servants' latrines, and to see that the house and compound are kept in a clean, sanitary condition. He must also see that the filters are properly cleaned, and should flies abound in the house, their source should be diligently sought for, or, if it cannot be found and dealt with, the Sanitary Authority should be informed. He should also see that the whole household keep themselves strictly clean, especially the cooks.

With regard to food and drink, care should be taken that all cooking and serving vessels are thoroughly cleansed with boiling water, and that kitchen cloths are washed in a solution of cyllin or carbolic acid. Especial care should be taken with regard to the ice-safe, which is apt to become coated internally with green slime, which may cause diarrhœa. This ice-safe must be thoroughly cleaned with hot soda and water, and exposed to the sun at least once a week. Food must not be stored near latrines, and must be protected from flies and ants, and the rooms and cupboards in which it is placed must be thoroughly cleansed with soda and hot water at least once a week.

All water must be boiled and filtered, and stored in covered vessels, and all milk must be boiled and carefully protected from flies and other insects. Care should be taken that good milk is procured. No uncooked vegetables or salads should be used; fruit must be sparingly indulged in, and unripe fruit, especially melons, must be avoided. Balfour advises that jellies in particular should not be used during a dangerous season. Weak tea and lime drinks made with boiling water should be used as beverages.

All cases of illness, but especially diarrhœa, must be promptly treated by a medical man.

With regard to prophylactics, eucalyptus oil in 10-minim doses twice daily has been strongly recommended by some authors, but the most usual prophylactic is a protective inoculation, which was first introduced by Ferran in Spain, and has been studied and improved by Haffkine and Gamaleia; by Tamancheff, who added 0·5 per cent. carbolic acid to the sterilized prophylactic; and by Strong and others.

Vaccines.—Haffkine originally used two prophylactics—a weak and a strong—with the idea that the strong would produce too violent a local reaction: but this proving to be wrong, only the strong is now used. This prophylactic is prepared by intensifying the virulence of the vibrios by passing them through a series of rabbits, and then growing on agar, from which the growth is washed off by sterile broth which is made up to 8 c.c., of which one is injected hypodermically into the flank as a dose. There is some local reaction in the form of redness, swelling, and pain, and some general febrile reaction. The result is that after an initial diminution of the resistance against the disease this becomes considerably increased after the fifth day. Haffkine's statistics show that it diminishes by one-tenth the liability to the disease, and increases the chance of surviving if attacked. Thus, according to Powell, in 6,549 non-vaccinated there were 198 cases and 124 deaths, and in 5,778 vaccinated there were 27 cases and 14 deaths. Vaccination confers a partial immunity, which is said to last about fourteen months, after which it diminishes, and finally disappears. Re-vaccination is, therefore, necessary after this period.

Strong's method is to spray agar which is contained in large flat-sided flasks with a twenty-four-hour-old culture of the vibrio in broth, and then to incubate the flasks at 37° C. for twenty hours, and to suspend the subsequent growth in sterile water, which is first heated to 60° C. for one to twenty-four hours, then incubated at 37° C. for two to five days, and then filtered through a Reichel candle. Two c.c. (the equivalent of 10,000 units of immunity in a rabbit) of the filtrate, which must be sterile, are inoculated. This prophylactic, which is said to be capable of being kept for a year, produces no local reaction, and but slight general reaction, and increases the bactericidal and agglutinative powers of the serum considerably. Strong considers that it contains receptors separated from the vibrios, and that it probably acts by increasing the bactericidal and antitoxic powers of the epithelial cells of the mucosa of the alimentary canal.

One of us has prepared an attenuated live vaccine by heating emulsions of agar cultures to 45° C. or 48° C. for one hour.

A nucleo-proteid vaccine, according to Lustig and Galeotti's method, can also be prepared.

Tetravaccine (T.A.B.C.)—This is a vaccine prepared and used by Castellani since 1909, and now frequently employed in various countries as a prophylactic measure against cholera as well as typhoid and the paratyphoid fevers. It has been adopted in the Serbian Army since 1915. It is prepared as follows:—

The growth of typhoid cultures is washed off with sterile 0·85 per cent. salt solution, to which 0·5 per cent. carbolic acid has been added; the emulsion so obtained is stored at room temperature (18° to 20° C.) for twenty-four hours, and then standardized. To standardize it the germs are counted by using a Thoma-Zeiss apparatus, and sufficient carbolic salt solution is added to bring the number of germs down to 2,000 millions per cubic centimetre. The standardized emulsion is tested for sterility. The same procedure is carried out with paratyphoid A and paratyphoid B cultures, these two emulsions being also standardized to contain 1,000 million germs per cubic centimetre. The above procedure is also carried out with cholera, the emulsion of which, however, is standardized to contain 4,000 million germs per cubic centimetre. The four standardized emulsions when found sterile are mixed together in equal proportions, and the vaccine will therefore contain per cubic centimetre:—

Typhoid .	500 millions
Paratyphoid A	250 ,,
Paratyphoid B	
Cholera .	

Of this mixture, 0·5 to 0·6 c.cm. are given under the skin of the arm, or better into the loose tissue below the angle of the scapula, the first time, and double the amount a week later. A third dose, also ½ c.cm., given two weeks after the first, is of advantage, but not essential for practical purposes. The amount of agglutinins for each germ is about the same as if monovalent vaccine had been injected. The protection for cholera seems to last for about six months.

Castellani has prepared also a glycero-tetravaccine containing 2 per cent. pure glycerine and standardized as to contain per c c. typhoid 2,000 millions, paratyphoid A 100 millions, paratyphoid B 1,000 millions, cholera 4,000 millions. Of this vaccine only one inoculation of 1 c.c. is given.

A *pentavaccine* having in addition 300 millions of *B. pestis* may also be prepared. The effect of the vaccine in man lasts for several months (six to seven).

Public Prophylaxis.—It is the duty of the State to attempt to ward off cholera by preventing human beings introducing the germ. This involves the careful watching of the frontiers, especially along the lines of intercommunication, whether roads, railways, or waterways. Under the last heading must be included ships, boats, and rafts, for it must be remembered that cholera is very apt to be introduced by persons travelling along rivers.

Any suspicious case must be detained for five days in quarantine in suitable isolation hospitals erected near the frontiers, while the sick must be tended in special hospitals with all the precautions to be mentioned later.

Merchandise does not, as a rule, require any disinfection, unless there is reason to suspect that some of it has been fæcally contaminated from a case.

When an epidemic begins, the first duty is to form a special Cholera Board to deal with the outbreak, and this Board should be composed of financial and legal authorities, as well as of doctors and bacteriologists. This Board will form the central authority for the control of the epidemic. All suspicious cases must be reported to this central authority at once.

Then central and outlying bacteriological stations must be provided, and special hospitals and isolation hospitals built, and, if possible, nurses and medical men obtained who have some practical knowledge of the disease. If time permits, it is as well to have these vaccinated against the disease, but it should be remembered that five days must elapse before the immunity is effective.

Arrangements must then be made for the prompt bacteriological diagnosis of cases, for the prompt treatment of all disorders, especially intestinal, and extra dispensaries must be opened, and the public informed of the necessity of availing themselves of these medical arrangements. If necessary, a house-to-house inspection should be made, in order to find out if there are mild concealed cases, and nobody should be buried without a proper medical certificate.

All patients must be removed to the hospitals, and the houses disinfected with the Clayton gas apparatus, in order to kill not merely the germs, but also the flies and ants. If this is not available, formalin sprays, together with burning sulphur, may be used. Fomites should be carefully disinfected, and persons attending the sick must avoid infection by careful disinfection of the hands and by wearing overalls.

The dejecta of patients should be carefully disinfected with cyllin or carbolic acid, and no patient should be liberated from the hospital until bacteriological examinations of his fæces on three successive days are negative. This is a most necessary precaution, because otherwise he may spread the germs broadcast for a period of about six weeks at least.

Care must be taken to disinfect and bury the dead with least chance of the infection spreading. Cremation should be encouraged in preference to burial.

A systematic search must be made for the origin of the infection, and drinking-water, well-water, etc., must be regularly examined bacteriologically. Dangerous wells must be closed, and all wells may be Hankenized—*i.e.*, disinfected with permanganate of potash.

The milk, ice, and aerated waters should be taken under the municipal control, and not merely must care be taken that they are pure, but they must be tested bacteriologically from time to time.

Vegetables must be inspected, and the place where they are grown ascertained and inspected, in order to find whether there is fæcal pollution. A crusade must be made against flies and dirt in general. The disposal of sewage should, of course, have been dealt with before the epidemic has occurred; but if it is defective, attempts should be made to remedy this as far as possible, and a scheme at once started for proper collection and disposal.

Bathing-places must be carefully inspected, and bad places closed, and only pure water allowed to be used. No washing must be allowed near wells. Drugs must be given free, and means for inoculation of the prophylactic provided on a large scale.

When the epidemic is past, the sanitary defects found out during its course should be remedied, and not forgotten until another outbreak occurs.

Summary of Prophylactic Measures.

Public Prophylaxis :—

1. Protection of the frontiers by regular inspection posts and quarantine stations.
2. A central Cholera Board, with full staff and apparatus for bacteriological disinfection and hospital work.
3. Instruction of the populace by means of pamphlets.
4. House-to-house search for cases.
5. Search for carriers and sources of infection.
6. Distribution of medicines and disinfectants.
7. Provision of medical aid which can be readily obtained by anyone.
8. Crusade against house flies.

Private Prophylaxis :—

1. Personal cleanliness.
2. Avoidance of foods liable to be contaminated or to cause diarrhœa.
3. Avoidance of pollution of foods, especially by flies.
4. Filtration and boiling of all water used for cooking, drinking, etc. Filters to be kept strictly clean.
5. Boiling of milk and protection against flies.
6. Clean, sanitary dwelling free from flies.
7. Anti-cholera vaccination, repeated yearly in endemic centres.
8. Immediate application for medical aid in case of diarrhœal illness of any description.

PARACHOLERA.

Synonym.—N'diank (Senegal).

Definition.—Paracholera, a term first introduced by Castellani, indicates an acute attack of colic and diarrhœa, with or without rice-water motions, which resembles cholera in the severity of the symptoms, but differs therefrom in that its causal organism is a vibrio different from *Vibrio choleræ* Koch.

Remarks.—The work of Castellani, Thiroux, Lamas, Greig, Orticoni, Chalmers and Waterfield, and many others, has demonstrated

the existence of a clinical entity differing from true cholera mainly in the fact that the causal organism is not the cholera vibrio.

Ætiology.—The organisms which have been isolated from cases of paracholera are:—

Vibrio kegallensis vel paracholeræ Castellani in Ceylon.

Vibrio freseris Lamas in Spain.

Vibrio gindha Pfeiffer, by Chalmers and Waterfield, in 1916, in the Anglo-Egyptian Sudan.

Orticoni's vibrio in Marseilles in 1911.

Symptomatology.—Clinically the symptoms resemble those of Asiatic cholera, and as such the cases are generally diagnosed. The motions are generally of the rice-water type, but are sometimes slightly greenish, therein differing from true cholera.

Treatment.—This is the same as for cholera.

PSEUDOCHOLERA.

Synonyms.—Choleraic diarrhœa, called ptomaine poisoning, Serous diarrhœa, Trench diarrhœa.

Definition.—Pseudocholera is an acute attack of serous diarrhœa which resembles cholera and paracholera in its symptoms, but differs therefrom in being due to various causes, none of which is a vibrio.

Remarks.—Cases of profuse serous diarrhœa associated with algidity, muscular cramps, and in general showing symptoms resembling cholera or paracholera, are not rare, in our experience, in tropical and subtropical lands and war zones.

Ætiology.—The causal agents are very various—*e.g.*, food poisoning, generally caused by bacilli of the *aertrycke* type; serous diarrhœa, caused by bacilli of the *dysentery* group: atypical subtertian *malaria*; certain *poisons*. We will now consider the symptomatology of these varieties.

Food-Poisoning Pseudocholera.

This form of pseudocholera is generally due to *B. aertrycke.* The cases are of mild or moderate severity, and are often termed 'ptomaine poisoning.' The onset is acute, with severe abdominal pain, furred tongue, and diarrhœa. The motions do not contain blood or mucus, nor are they usually of the nature of rice-water, but in the more severe cases the stools are choleraic and there may be algidity and cramp.

Bacillus aertrycke can be differentiated from *B. paratyphosus B* by means of Castellani's absorption test. Broughton Alcock has described several varieties of *B. aertrycke* which can be distinguished by this method. For its biochemical characters see table of intestinal bacteria, p. 944.

Dysenteric Pseudocholera.

Castellani some years ago showed that the type of choleraic diarrhœa, called serous diarrhœa, was often due to bacilli of the dysentery group, and therefore of dysenteric origin. Recently Besredka in cases of so-called *trench choleraic diarrhœa* has also found bacilli of the dysentery group. The onset is sudden, and at times the symptoms may be mild, but more commonly they are severe. The patient passes a number of serous motions resembling those of cholera. There may be algidity, cramps, and the illness may terminate in death. In most cases, however, the motions are now and then tinged with blood, which arouses suspicion as to its dysenteric nature. Microscopical examination of a fresh preparation of the fæces may show a few red cells and leucocytes, instead of the epithelial desquamation found in true cholera. Bacteriological examination demonstrates the presence of dysentery bacilli and the absence of cholera and paracholera vibrios.

Malarial Pseudocholera.

This type is not rare in the tropics. The onset is sudden, with profuse serous diarrhœa, algidity, and other symptoms closely resembling true cholera (see p. 1177)..

If the spleen is enlarged the diagnosis is facilitated, though true cholera may develop in cases of malarial infection. Microscopical examination of the blood and bacteriological investigation of the fæces are also useful in demonstrating the presence of malarial parasites and the absence of cholera and paracholera vibrios. Intramuscular injections of quinine quickly cures this type of choleraic diarrhœa.

Pseudocholera caused by Poisons.

This is most usually caused by *arsenic*, which is commonly in use in the tropics, especially in Ceylon, where it can be bought in the local markets. The diagnosis may be established by the history and by chemical analysis of the vomit and fæces and negative bacteriological examination.

CHAPTER LXXVIII

THE DYSENTERIES

The term ‘dysentery’—Dysentery and dysenteric diarrhœa—Dysenteries caused by animal parasites—Protozoal dysenteries—Amœbic dysentery—Laveranic dysentery—Leishmanic dysentery—Ciliar dysenteries—Balantidic dysentery—Spirochætic dysentery—Entoplasmic dysentery—Platyhelminthic dysenteries—Nemathelminthic dysenteries—Arthropodic dysenteries—Dysenteries caused by bacteria—Pseudo-dysenteries—References.

The Term ‘Dysentery.’—The term ‘dysentery’ is derived from *δυσεντερία*, signifying a bowel trouble, and was first employed by Hippocrates. As used at present, it covers a large number of distinct affections, induced by various species of animal and vegetal parasites. In England it used to be called the *Bloody flux*, in France *Ténesme*, and in Italy *Flusso sanguigno*. The Latin equivalent is *Tormina*, the German *Ruhr*; while the native terms applied to it are too numerous to be considered here, but we may mention the Sinhalese term *Lehedanpachanai* (*Leh* = blood, *hedan* = mucus, *pachanai* = diarrhœa), and the Indian term, *Rattam-seedam-banthala-porado* or *Wayatholechell*.

Dysentery and Dysenteric Diarrhœa.—The occurrence of a bowel disease in which blood appeared in the motions was well known to the ancients, for descriptions of such a condition can be found in the works of the old authors Charaka and Susruta, in which dysentery was called ‘Atisar,’ and acute dysentery ‘Ama-apaka,’ while the chronic variety was called ‘Pakitsar.’

Hippocrates recognized two distinct types of disease of the bowels—one characterized by the number and fluidity of the motions, which he called *διαῤῥοία*, and the other, by the presence of blood in the motions, which he termed *δυσεντερία*.

At first the term ‘dysentery’ included any disease in which there was a discharge of blood *per anum*, but Aretæus, Celsus, Archigenes, Galen, and other ancient physicians, soon differentiated the disease more clearly by emphasizing the fact that there should be mucus as well as blood in the motions, and that the symptoms of tormina and tenesmus must be present. They further stated that the disease was due to an ulcerated condition of the bowels, and the contagious nature of the malady was early recognized and it was thought that its epidemics were due to miasmata. According to these ancient writers, in order to make the diagnosis of dysentery, it was necessary to have blood and mucus in the motions. Recent investigations have, however, shown that certain cases of diarrhœa and dysentery are brought about by the same organism, and that a form of diarrhœa which may be called dysenteric diarrhœa is only one phase of the clinical appearances of a dysentery, and is ætiologically in no way different from what might be termed a true dysentery, except in the severity of the symptoms and the post-mortem appearances. Briefly, dysenteric diarrhœas are dysentery under a somewhat different clinical aspect—viz., the stools do not contain blood and mucus, although the complaint is due to the same organisms as true dysentery. Hence it is not expedient to attempt to classify dysenteries by their clinical symptoms or by their post-mortem appearances, and any rational classification and description of the complaint must be based on the causation.

We therefore classify dysenteries and dysenteric diarrhœas into:—

A. Dysenteries caused by Animal Parasites:—
  I. The Protozoal Dysenteries.
  II. The Platyhelminthic Dysenteries.
  III. The Nemathelminthic Dysenteries.
  IV. The Arthropodic Dysenteries.
B. Dysenteries caused by Bacteria.
C. Pseudo-dysenteries.

By the last expression we mean such forms of the complaint as may be due to the irritation of fish-bones, glass, cancer, or inflammations of organs adjoining the alimentary canal.

A. DYSENTERIES CAUSED BY ANIMAL PARASITES.

I. THE PROTOZOAL DYSENTERIES.

The protozoal dysenteries are classified into:—

(*a*) Amœbic Dysentery.
(*b*) Laveranic Dysentery.
(*c*) Leishmanic Dysentery.
(*d*) Ciliar Dysenteries.
(*e*) Balantidic Dysentery.
(*f*) Spirochætic Dysentery.
(*g*) Entoplasmic Dysentery.

With regard to the term 'amœbic dysentery,' we prefer this term as less likely to be altered rather than the more correct nomenclature Loeschial dysentery or Loeschiasis.

(*a*) Amœbic Dysentery.

Synonyms.—*Loeschiasis*, *Loeschial dysentery*, Entamœbiasis, Amœbiasis, Entamœbic dysentery, Amœbic enteritis, Amœbic colitis. *French:* Dysenterie Amibienne, Dysenterie à Amibes. *Italian:* Dissenteria Amebica. *German:* Amöbenruhr.

Definition.—Amœbic dysentery is an acute or chronic specific disease of the intestine, caused most commonly by *Loeschia histolytica* Schaudinn, 1903, and possibly by other species. These amœbæ enter the body with food or water, and produce colitis, rectitis, and enteritis, characterized by the passage of frequent motions, which generally contain blood and mucus, and are associated with abdominal pain and tenesmus. At times they also produce abscesses in the liver and other parts of the body.

History.—In 1860 Lambl noticed amœbæ in the motions of a child suffering from diarrhœa, and in 1870 Lewis found the same organisms in the motions of cholera patients; while Loesch, in 1875, gave a careful description of certain amœbæ which he found in the motions of a man suffering from chronic diarrhœa. Loesch's drawing signifies that he saw the organism which we call now *Loeschia histolytica*. Further, he found that solutions of quinine of a strength of 1 in 5,000, when injected *per rectum*, temporarily benefited his patient, who, however, subsequently died of pneumonia, when a post-mortem revealed that the bowels were ulcerated. Loesch was able to infect dogs; but, on the other hand, Grassi, and later Cunningham and Lewis, showed that the motions of healthy people also contained amœbæ. Koch, in 1883, found amœbæ in the ulcers in cases of dysentery in Egypt, and Kartulis began a series of investigations, which finally ended by his defining the types of dysentery as 'endemic,' due to amœbæ, and 'epidemic,' due to bacteria. In 1891 Councilman and Lafleur introduced the term 'amœbic dysentery,' and Quincke, Roos, Vivaldi, and many others published experimental researches on the infection of animals by amœbæ and the production of dysentery.

In the meanwhile a prolonged discussion took place, some observers denying, and others asserting, the pathogenicity of the amœbæ. Kruse and Pasquale were the first to throw light upon this difference of opinion by suggesting that both theories might be correct, and that there might be two species of amœbæ, one pathogenic and the other harmless; but this was not finally settled until the researches of Casagrandi and Barbagallo, together with those of Jürgens, were confirmed and greatly extended by Schaudinn, who showed that there were two forms of amœbæ quite distinct from one another—viz., a *Loeschia coli* Loesch, which was harmless, and another, *L. histolytica* Schaudinn, which was the true cause of entamœbic dysentery.

During recent years the labours of Hartmann, Whitmore, Wenyon, Fantham and Porter, Dobell and others, have proved that the amœba which most commonly causes dysentery is *L. histolytica*, and that the other forms of amœbæ described in dysentery by Viereck (*L. tetragena*) and other observers are different stages of this amœba, the cysts of which can be carried by domestic flies.

Climatology.—Amœbic dysentery is found throughout the tropical world, and also occurs in the Temperate Zone. In general terms it may be stated that amœbic dysentery is common in tropical and subtropical Africa, especially in Senegambia, Algeria, and Egypt. It is common in Mauritius and Ceylon, and is possibly not as rare in India as it is alleged to be. It is common in China, Indo-China, and the Philippines, and not infrequent in North America, but is said to be rare in Central America, in the West Indies, and the Guianas, while common in Brazil and Chili. In Europe it is endemic in Russia and Germany, and fairly frequently met with in the south, especially in Italy and in the Balkans. Sporadic indigenous cases have been reported also from Great Britain, where carriers of *Loeschia histolytica* cysts are not very rare especially among miners.

Our observations do not lend support to the theory that amœbic dysentery is more common in the hills than in the plains of the tropics, as we have frequently met with it in persons residing in the low country. We have noted the disease all the year round, but it would appear to be more prevalent towards the end of the dry and the beginning of the wet seasons, which probably merely means that the chance of drinking polluted water is greater at that time, for though the climatological characters are not well understood, the disease appears to bear a relationship to contaminated water, though flies are also very important.

Amœbic dysentery is generally endemic, and does not spread in epidemic, still less in pandemic, form. Probably, as medical science advances, it will be found to be of more frequent occurrence and of wide distribution.

Ætiology.—The prevalent opinion at the present time is that amœbic dysentery is generally caused by *Loeschia histolytica* Schaudinn, 1903, but the possibility is not excluded of there being other pathogenic *Loeschiæ*. The life-histories of the various species, as far as they are known, have already been described in Chapter XVII., p. 285. The most common source of infection is the drinking-water, which has been contaminated by fæces, and contaminated food, and especially green vegetables, which may be infected principally by the agency of flies carrying the cysts in their intestine and depositing them upon the food, and less frequently by actual human fæcal contamination.

Woodcock has called attention to the importance of a hot, damp climate as a factor in the spread of amœbic dysentery, as cysts survive much longer in a hot, damp climate than in a dry climate. Cysts cannot withstand drying; while the experiments of Penfold, Woodcock and Drew have shown that cysts of *Loeschia histolytica* can retain their vitality for more than a fortnight in water.

There does not appear to be any well-established racial or age predisposition, but the disease is less common in women than in men, perhaps because they are in some way less exposed to infection.

Pathology.—The spores of the amœbæ enter the body by the drinking-water, and by food contaminated with cysts, often deposited by flies, and produce the young amœbæ on arrival in the large bowel. These young forms enter the mucosa, probably by passing between the cells lining Lieberkühn's follicles, and then, entering the lymphatics, make their way through the muscularis mucosæ into the submucosa, where they live and feed upon the tissue cells, red cells, and perhaps leucocytes. They, however, invade not merely the tissue of the submucosa, but also the radicles of the portal vein, and at times the branches of the mesenteric arteries, in which they may cause thrombosis. From the radicles of the portal vein they may be carried to the liver, and cause hepatitis and hepatic abscess.

In the submucosa they induce cellular and œdematous infiltrations, which cause the mucosa to project in the form of small elevations, which generally show a minute blackish point or slough at the summit. This slough is cast off, and a small ulcer is formed, which rapidly deepens until it extends into the submucosa. These ulcers become infected with bacteria, and quickly extend by the joint action of the bacteria and the amœbæ, forming roundish or oval ulcers with undermined edges: in the latter case the long axis of the ulcer lies transverse to the direction of the bowel. These ulcers may deepen until the muscular and the peritoneal coats are exposed, and even perforated, which, of course, leads to peritonitis or abscess formation, according to the position of the perforation.

Amœbic dysentery would appear to undergo in many cases no spontaneous cure, but may at times remain quiescent, forming a type of latent amœbic dysentery, which may be found accidentally while performing an autopsy. When the ulcers heal, which they do by the formation of connective tissue, a distinct scar is formed, which is often black in colour from the action of the sulphuretted hydrogen of the bowel upon the iron of the blood. When cicatrization takes place, the lumen of the bowel may be constricted, causing stenosis and obstinate constipation. Peritonitic adhesions are also very common, binding the large bowel to the viscera or walls of the abdomen and pelvis.

Sometimes, when the infection is severe, the bowel becomes gangrenous; at other times the amœbæ may be carried to the liver or other parts of the body, and form abscesses, which, though most commonly met with in the liver, may still occur in the spleen, the salivary glands, and elsewhere.

Morbid Anatomy.—Usually the body of a person dying from amœbic dysentery is emaciated, and the abdomen is sunken. Rigor mortis begins, and passes off early, and decomposition sets in quickly. On opening the abdomen, it is noticed that the tissues are dry, and that a peculiar odour is perceived; the omentum may be normal or congested, and may or may not be adherent. The coils of the small intestines are usually normal, but may be congested. The large intestine is generally contracted and thickened, but may be gangrenous in places or along its entire length. There may be perforation and purulent peritonitis. The mesocolon may be congested and œdematous, or thin and fibrous, and adhesions to various organs may be noted. The mesocolic glands are usually enlarged and hyperæmic. The colon may be found adherent to the liver, the spleen, or the wall of the pelvis, while internally the mucosa will be found to be reddened and inflamed, and to show more or less numerous areas of ulceration and infiltration. These areas are most commonly found in the cæcum, the hepatic flexure, and the sigmoid colon, but may occur anywhere along the course of the large intestine. In places small nodules surrounded by a ring of dilated vessels may be observed, between which the mucosa may or may not be normal, while the nodules may show superficial or deep ulceration. Deeper circular or oval ulcers may be noted with their surface covered with a dark reddish slough, their edges undermined, and their base formed by the muscular coats. In the case of the oval ulcers, the longer diameter lies transverse to the long diameter of the bowel, as a rule. The peritoneal coat may be normal, inflamed, or softened and gangrenous. Usually the muscular coat is thickened, as are the remains of the submucosa. Scrapings from these ulcers reveal blood cells, leucocytes, bacteria, and amœbæ. The small intestine may show small bright red nodules, and the Peyer's patches may be enlarged. The vermiform appendix is usually normal, but occasionally may be ulcerated.

FIG. 762.—THE COLON IN A CASE OF AMŒBIC DYSENTERY.

The liver is often fatty, but may be congested and inflamed, or may show one or more abscesses. The pancreas is generally normal, but may be cirrhotic in chronic cases. The spleen is also usually normal, but may contain an abscess; the kidneys often show signs of parenchymatous inflammation. The heart and lungs are generally normal, but the former may be fatty or show brown atrophy, and the latter, especially the right lung, may show a hepato-pulmonary abscess.

Symptomatology.—The symptomatology of amœbic dysentery may be classified into:—

1. Acute Type.
2. Chronic Type.
3. Latent Type.
4. Mixed Type.

1. *Acute Type.*—The onset is abrupt, but may occasionally be preceded for a few days by slight diarrhœa, alternating with constipation. Pain is felt in the lower part of the abdomen, which may become very severe, while the motions are attended with much griping and straining. These motions, which rarely exceed thirty per diem, contain blood and mucus, and occasionally greenish material, and when examined by the microscope reveal leucocytes, mucus, Charcot-Leyden crystals, amœbæ, bacteria, and at times shreds of tissue.

The tongue is moist, and often coated with a white fur, and there is usually anorexia, and there may be nausea and vomiting, while digestion is usually much impaired. The abdomen is sunken, the liver and spleen normal, but tenderness is felt on pressure along the whole or a part of the large bowel.

The examination of the heart and lungs reveals, as a rule, no abnormality, but the pulse and respirations are quickened. The microscopical examination of the blood usually shows that the red cells are diminished, and sometimes that there is leucocytosis (upwards of 20,000 per cubic millimetre), and at times, as first pointed out by Billet, the number of eosinophiles is distinctly increased, even when there is no concomitant helminthiasis.

The urine is diminished in quantity, and sometimes contains albumen and casts; but the skin is generally normal, though there is often some fever of a remittent type, which, however, may be entirely absent.

When the temperature falls to normal, and the pain and tenderness abate, these may be favourable signs, or may be merely a prelude to a gangrenous complication or a hæmorrhage. If recovery is to take place, the motions become less frequent and more fæculent, and contain less blood and mucus, and gradually improve until normal motions are passed. If death takes place, which usually happens about the end of the first week, and ten days from the commencement, it is generally caused by exhaustion, or much more rarely by perforation and peritonitis or hæmorrhage.

2. *Chronic Type.*—This may follow an acute attack, or, in many cases, may begin quite insidiously, the symptoms being merely

those of diarrhœa, associated at times with abdominal pain and the passage of fæculent motions mixed with mucus and sometimes streaked with blood, while in the intervals between these exacerbations there may be constipation. An exacerbation is usually ushered in by pain in the abdomen, slight fever, griping, and tenesmus, and passage of blood and mucus in the motions, while the fæces contain small greyish masses, in which the amœbæ may be found. The number of motions per diem is not excessive, and may be only twelve to fourteen. Usually they are passed somewhat more frequently at night than in the day. Gangrenous complications may, however, occur at any time in the course of an exacerbation, or, indeed, during any stage of this type, when large sloughs, smelling offensively, may be passed with the motions. Chronic dysentery may persist for years, and cause the patient to slowly emaciate. The blood, as shown by Chalmers and Archibald, often shows an increase in the large mononuclears.

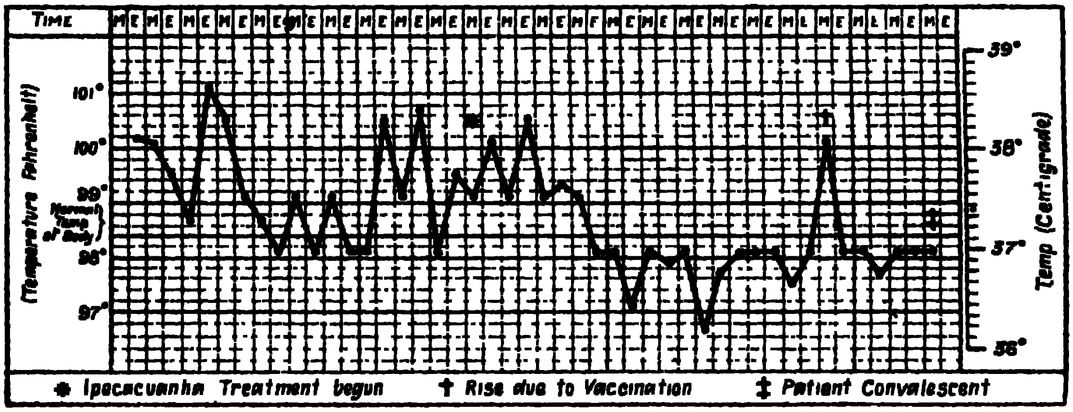

FIG. 763.—TEMPERATURE CHART OF A CASE OF AMŒBIC DYSENTERY COMPLICATED BY HEPATITIS.

3. *Latent Type.*—We have several times met with cases in which, though dysenteric symptoms were absent, still, amœbæ were present in the motions, and others in which dysenteric ulcers were only discovered accidentally on post-mortem examination, the death being due to other causes. This latent condition is important, as it can easily lead to an acute attack or to liver abscess, and no doubt these 'entamœbic carriers,' as has been noted by Martini, Vincent, and others, are a source of the dissemination of the infection.

4. *Mixed Type.*—These are cases in which there is a mixed infection of *Loeschia histolytica* and the Shiga-Kruse bacillus. Usually in these cases the motions are numerous from the first, and there is considerable fever, nausea, vomiting, and great constitutional disturbance. The motions are apt to be very offensive, and to contain sloughs, indicating a gangrenous condition of the bowel. Exhaustion may come on early, and the patient may die delirious or comatose, or, more rarely, from peritonitis, with or without perforation. More rarely improvement sets in, and the disease becomes chronic.

Amœbic Fever or General Amœbiasis.—This term has been applied to certain cases of *L. histolytica* infections in which there is fever, but no dysenteric symptoms and no sign of hepatitis. A few cysts are generally found in the stools, and emetine induces a prompt disappearance of the fever.

Complications.—The most usual complication is hepatitis and hepatic abscess; more rarely gangrene of the bowel and peritonitis may supervene during an attack; while hæmorrhage is a most unusual complication. The hepatitis is recognized by the tenderness in the right hypochondrium and by the rise in the temperature, but it and the hepatic abscess will be discussed in a subsequent chapter. In Ceylon we have observed cases of mixed infection, dysentery and enteric, the two infections developing apparently contemporaneously.

Sequelæ.—The important sequel to an attack of amœbic dysentery is liver abscess, but abscesses in other parts of the body such as the spleen may be met with. Stenosis of the sigmoid colon, due to cicatrization of the healing ulcers, is well known, and will be dealt with under the heading of Bacterial Dysentery. Sprue is often said to be a sequel of dysentery, but this must be considered to be doubtful. Certain authors have described a persistent bradycardia.

Diagnosis.—The diagnosis between bacterial and amœbic dysentery by clinical phenomena only is, in our opinion, impossible in most cases, though several observers have attempted to define some differential points. These authors state that amœbic dysentery is to be distinguished from bacillary dysentery by its chronic course, its rare pyrexia, and the absence of toxic symptoms, while it is often followed by liver abscess. Apart from the last feature, the other so-called differential signs have, in our experience, no importance, as we have come across extremely acute cases of amœbic dysentery with fever and toxic symptoms.

The only certain method of diagnosis is by the discovery of *Loeschia histolytica* in the stools, and this should be done by picking out and examining any mucus which may be seen. It is of practical importance to distinguish between *L. histolytica* and the harmless *L. coli*, and this differentiation may at times be difficult. The former is often larger, and possesses an ectoplasm, which is easily differentiated from the endoplasm; it is more actively motile than *L. coli*, and often contains erythrocytes, which is the most important character. The nucleus of *L. histolytica* is eccentric, small, and generally indistinct, does not stain deeply, and has very little chromatin (see p. 313).

In order to expedite the diagnosis the French method is to add a drop of a 1 per cent. solution of methylene blue to the mucus before placing on the coverslip, when the pus and epithelial cells will be stained, and the amœbæ more easily recognized as unstained, clear objects.

The diagnosis of latent cases and of carriers is based on the finding of the characteristic histolytica cysts containing four nuclei. It is important to note that cysts are not often seen during the acute attacks with blood and muco-pus.

In the search for cysts, only a small quantity of material should be used well diluted with saline. The addition of a little iodine solution is useful, as it makes the nuclei more visible. Dead cysts are easily stained by eosin, while live ones are not.

Cysts of *Loeschia histolytica* have to be differentiated principally from cysts of *L. coli*, *Vahlkamfia nana*, amœbæ of *Limax* type, *Chilomastix*, *Lamblia*, and from the structures known as *Blastocystis hominis*. The characters of all these cysts have been given in detail in Chapters XVII. and XVIII. For diagnostic purposes it is sufficient to remember the following:—

I. Cysts of *L. histolytica* in fresh preparations from stools mixed with salt solution appear as spherical, greenish, very refractile bodies 10-14 microns in diameter, containing four nuclei (at times two) and one or two highly refractile homogeneous rods known as chromidial bodies. Several vacuoles may be present. Dobell and others have called attention to the fact that the size may vary a great deal, there being races of *histolytica* (*minuta* type) giving rise to much smaller cysts, 7 to 9 microns, and others to much larger ones, 12 to 20 microns.

II. Cysts of *L. coli* vary between 15 and 20 microns, are rarely larger, occasionally smaller. They are clear spherical bodies of sharp outline, less refractile than those of *L. histolytica*. They contain 8 *nuclei*, which appear as faint granular rings with a central dot (karyosome). Often only one vacuole.

III. Cysts of *Vahlkampia nana* are oval or spherical structures 7 to 9 microns in diameter, with one, two, or four nuclei, very rarely eight; in addition, a variable number of highly refringent granules and sometimes a large dull inclusion (glycogen). There is absence of chromidial bodies, and this distinguishes the cyst at once from the small ones of *L. histolytica*.

IV. Cysts of amœbæ of *Limax* type are found in stale stools, are always small, uninucleated, and often have a thick wall of brownish colour.

V. Cysts of *Chilomastix mesnili* are often lemon-shaped, and are characterized by the presence of the chromatic rod (parabasal).

VI. Cysts of *Giardia intestinalis* are easily recognized by their egg-shaped appearance; they are about 14 microns in length and very transparent, so that the lamblia can be seen within it with the characteristic central paired rod-like structure in which originate the four pairs of flagelli.

VII. Cysts of *Oicomonas*, *Bodo*, *Prowazekia* are very small, spherical, 6-8 microns in diameter, uninucleated, very similar to those of *Amœba limax*, but the wall is not so thick nor of brownish colour, and the outline is more regular. Sometimes, however, it is impossible to distinguish these cysts from those of *Amœba limax*. They can always be differentiated, however, from those of *L. histolytica*, as they are very small and uninucleated.

VIII. The structures known as *Blastocystis hominis*—considered by some authors to be vegetal organisms—are more or less spherical, 5 to 15 microns in diameter, with a more delicate capsule than the cysts of Loeschiæ, and contain a very large vacuole, which reduces the cytoplasm to a narrow rim at one pole or both poles of the cyst.

IX. *Iodine cysts* (I-cysts). These structures, described by Wenyon and O'Connor, are generally roundish or oval, varying between 6 and 16 microns in diameter, and show frequently a iodophilic body, which tends to be rounded or lobed.

To facilitate the detection of cysts when these are in very small numbers various methods have been suggested, though in practice, as shown by Miss Porter, such methods take a great deal of time, and the results are not much better than those obtained by the simple immediate microscopical examination of several preparations. It is of advantage to give the patient a saline purge, and then one of the so-called enrichment methods of Cropper and others may be used: about 1 gramme of fæcal matter is mixed with 30 c.c. of salt solution in a conical glass, and ether added in the amount of about 10 to 20 per cent. The cysts are generally found in the supernatant fluid, and may be collected by centrifuging it.

Cysts maintain all their morphological characters for a very long period in fæcal matter mixed with a formalin solution (2 per cent.).

The presence in dysenteric stools of Charcot-Leyden crystals, as emphasized by Acton, points to the condition being of amœbic origin rather than bacterial, especially if there is scanty cellular exudate with preponderance of mononuclears.

Prognosis.—The prognosis in a case of amœbic dysentery must always be guarded, as there is the possibility of hepatic abscess as sequela of the mildest case, and the cure induced by emetine and ipecacuanha, though striking, is often merely clinical, complete sterilization not being attained. The prognosis is worst in the gangrenous cases, better in the acute, and still better in the mild chronic cases, but the danger of latency after an apparent cure must be remembered. In the acute type hiccough is an unfavourable sign, often indicating the approach of exhaustion and death.

Treatment.—It is of the utmost importance that the patient should be placed at rest in bed. For the same purpose the urine bottle and the bed-pan must be used. It is advisable to relieve the severe griping and straining by either a hypodermic injection of morphia or by small enemata of 40 minims of laudanum in 1 ounce of mucilage of starch, or by using a morphia (gr. ¼), or codeine (gr. ¼) suppository.

At first the bowels should be swept clean by a dose of castor oil (ʒiv. to ʒvi.), with or without a few minims of liquor opii sedativus, or a few doses of saline may be given during the first twenty-four hours (see Bacillary Dysentery). After the castor oil has acted, or simultaneously, the emetine treatment should be begun. One-third to half a grain of emetine hydrochloride, dissolved in sterile normal saline solution, should be administered as a hypodermic injection two or three times a day for several days. Emetine hydrobromide may also be used in the same dosage, but it is not quite so soluble. These drugs may be obtained in sterile tubes ready for injection. We have never seen any bad effects on the heart from the administration of emetine, but we have met with cases of dermatitis probably due thereto, while Dale and Low have noted diarrhœa after prolonged administration.

A combined subcutaneous and oral administration of emetine as recommended by Wenyon and O'Connor (one grain emetin by injection in the morning and a ½ grain emetine tablet at night) answers well, especially in subacute and chronic cases, and in carriers.

If emetine cannot be obtained, then ipecacuanha should be administered in 5-grain doses every three or six hours, or in larger doses (gr. x. to xx.) twice daily, given either in the form of 'membroids' or as pills coated with salol varnish or keratin. Our experiments *in vitro* tend to show that membroids and salol varnish do not dissolve freely in peptic juice, while they do so in pancreatic juice. The salol varnish was very efficient, but care must be taken that too thick a coating is not used, as it may not dissolve in pancreatic juice. Martindale's method of stearin-coated pills is good. In this way the nauseating effects of the ipecacuanha are often avoided without diminishing its efficiency, which is the result of using the de-emetized drug. Rarely the membroids and salol varnished pills may be passed unaltered in the motions, and in such cases ipecacuanha may be given in suspension in mucilage and chloroform water or in cachets or pills (gr. x. to xx. twice a day), and should be preceded a quarter of an hour by a dose of 15 minims of tincture of opium, in order to prevent the possible vomiting.

With regard to ipecacuanha, it is of great importance to use the best Brazilian, which should contain 72 per cent. of emetine (methyl-cephaeline) in its total alkaloids, the other alkaloids being cephaeline 26 per cent., and psychotrine 2 per cent.; on the other hand, Carthagena ipecacuanha contains cephaeline 57 per cent. and emetine only 40 per cent The powdered ipecacuanha should have an alkaloidal strength of 2 per cent.

Emetine and bismuth iodide has been introduced by Dale, and its efficacy has been confirmed by Low and Dobell and numerous other observers, including ourselves. It is especially useful in the treatment of carriers, inducing at times a complete disappearance of the cysts. It is useful also in amœbic hepatitis and general amœbiasis. It is given in gelatine capsules, one capsule containing gr. iii., at night for two or three weeks, or salol-coated tablets may be used. A shorter course seldom induces a cure. Not rarely the drug produces nausea and at times actual vomiting; in such cases the same precautions may be taken as when giving ipecacuanha.

When the acute symptoms have passed away, intestinal irrigations are useful, and should be administered every other day, or once or twice daily. We generally use a solution of tannic acid (3 to 5 in 1,000), or a solution of the bihydrochloride of quinine in varying strength from 1 in 5,000 to 1 in 750. About ½ to 3 pints should be very slowly injected by gravity from a glass douche vessel by means of a long soft rectal tube well greased with boric vaseline. This injection may be preceded by a cocaine or morphine (gr. ¼) suppository introduced half an hour previously.

Other substances used for rectal irrigations are:- Acetozone (1 in 2,000); alphozone (1 in 2,000); argentum nitras (1 in 2,000 or 1 in 1,000), useful in some very chronic cases; protargol (1 in 500). Creosote is recommended by Zanardini, and may be used by injecting 2 pints of 1 in 300 or 1 pint of 1 in 100. The injection, however, may be followed by symptoms of absorption—*e.g.*, dyspnœa and faintness. A solution of sodium hypochlorite may be used, 2 pints of 8 to 12 in 1,000 being recommended by Vincent once or twice a day, which is also useful for amœbic carriers.

In gangrenous dysentery the only chance of saving the life of the patient is to perform the operation of appendicostomy, and irrigate the whole lower bowel with quinine lotion (1 in 1,000) or collargol (1 in 500). The details of this operation are given under the heading Bacterial Dysenteries.

With regard to the treatment of symptoms, the most important is the relief of pain by hypodermic injections of morphia or by fomentations sprinkled with opium and applied to the abdomen. As the case progresses favourably, a bismuth mixture or tannalbin in cachets (gr. xx. every two to four hours) may be given, while the irrigation may be diminished and stopped, and finally a tonic may be prescribed.

We are strongly of opinion that the ipecacuanha or the emetine should continue to be given in smaller doses long after the dysenteric symptoms have disappeared, in order to prevent relapses, and possibly also the development of a liver abscess, which is the most dangerous sequel. Among the other drugs which have been recommended in the treatment of amœbic dysentery are *Simaruba officinalis* and the so-called *Kho-sam* powder.

The former is recommended by Manson to be used as a decoction which is prepared by taking simaruba bark, pomegranate fruit-rind, and gum arabic, 15 grammes of each, and placing in a litre of warm water, which is boiled till reduced to half its bulk, and of this decoction 1 ounce is taken three or four times a day. Shepherd and Lillie have cured, using preparations of chaparro or simaruba, 34 cases out of 80 cases of Loeschial carriers, refractory to emetine.

Nixon and Sellards and McIver have had good results by using preparations of Castela, a genus of the Simarubaceæ.

The Kho-sam powder is derived from the berries of *Brucia antidysenterica* and *B. sumatrana*, which grow in Indo-China. It is administered in pill form, 1 grain being given two to four times a day. Cinnamon has been often used in the past, and the compound extract of garcinia known also by the trade name of ambiasine is praised by several authors.

If cicatrization of the colon results with stenosis, then sigmoidoscopy must be performed, and the condition treated as described under Bacterial Dysentery. Liver abscess is considered separately. Abscesses in other parts of the body—*e.g.*, the spleen—are rarely met with, though it is possible that some of the inexplicable deep-seated abscesses may have their causation in amœbæ.

The *diet* should be the same as that to be described presently under the heading Bacterial Dysentery. During convalescence the food must be slowly and carefully increased, no acid or very warm substances being allowed.

Prophylaxis.—The prophylaxis consists in the drinking of only boiled and filtered water, and the avoidance of salads and uncooked vegetables and the prevention of fly infestation of food.

Stools of dysentery patients and carriers should be disinfected with cresol, 1 in 10.

Amœbæ, probably non-parasitic, were shown to exist in the drinking-water in Manila, and it was found that copper sulphate and filter-beds were useless. The only safeguard was to sterilize the water by boiling.

(*b*) Laveranic Dysentery.

Definition.—An acute enteritis and colitis caused by *Laverania malariæ* Laveran, and characterized by high fever, associated with the passage of frequent motions containing blood and mucus.

Symptomatology.—The attack usually begins suddenly, with high fever, great distress, and prostration. The tongue is coated, the abdomen tender, and many motions are passed containing blood and mucus. The spleen may or may not be palpable. Unless correctly treated, the condition becomes serious, and rapidly leads to the death of the patient.

Diagnosis.—The routine examination of the blood in all cases of tropical disease will prevent mistakes being made, as the presence of numerous subtertian parasites in the blood, with absence of amœbæ and dysenteric bacilli in the stools, will reveal the nature of the complaint. It should be kept in mind, however, that most cases of dysenteric colitis in malarial patients are, in reality, of amœbic and bacillary origin, and not of Laveranic origin.

Treatment.—Quinine should be given in large doses, best by intramuscular injection, and the intestinal symptoms first treated with castor oil or salines, and then with astringents, such as bismuth subnitrate, tannalbin, and salol.

(c) Leishmanic Dysentery.

Definition.—An acute enteritis and colitis caused by *Leishmania donovani* Laveran and Mesnil, and characterized by the passage of blood and mucus in the motions.

Symptomatology and Treatment.—As already mentioned in the chapter on Kala-Azar, dysenteric symptoms closely allied to true dysentery may appear during the course of that disease, and must be treated on the same lines as those laid down for the treatment of kala-azar, together with symptomatic treatment as indicated above. The diagnosis is based on the presence of Leishmanic bodies in the spleen or liver and absence of amœbæ and dysentery bacilli in the stools. True bacterial or amœbic dysentery is far from rare in cases of kala-azar.

(d) Ciliar Dysenteries.

One variety of the ciliar dysenteries may be briefly described—viz., that caused by *Balantidium coli* Malmsten. Other less known causes are *Colpoda cucullus* Schutz, *Balantidium minutum* Schaudinn, *Nyctotherus faba* Schaudinn, *Nyctotherus giganteus* P. Krause. Other possible causes are *Uronema caudatum* Dujardin, *Balantidium italicum* Sangiorgi and Ugdulena, and *Nyctotherus africanus* Castellani. For description of these parasites see p. 544.

(e) Balantidic Dysentery.

Definition.—An acute or chronic ulceration of the large intestine caused by *Balantidium coli* Malmsten, 1857.

History.—Leeuwenhoek originally discovered the parasite *Balantidium coli*, but Malmsten described and named it. The latter observer found it in the motions of a man suffering alternately from diarrhœa and constipation. Other cases have been recorded by Stieda, Henschen, Treille, Graziadei, Railliet, Blanchard, Collmann, Strong, Bowman, Manlove, Mason, and others.

FIG. 763A.- BALANTIDIUM COLI IN HUMAN FÆCES (× 520 DIAMETERS).

(Photomicrograph.)

Climatology.—The disease is known to occur in man in the Philippine Islands, Japan, and Europe, while the parasite is said to be constantly found in pigs. We have seen a case in Ceylon.

Ætiology.—The cause of the disease is *Balantidium coli* Malmsten, which may be different from the parasite found in pigs (for description of the parasite see Chapter XVIII., p. 547).

Pathology.—The method of infection is unknown. The parasite appears to enter the mucosa, in which it wanders, causing an inflammatory reaction and ulceration.

Morbid Anatomy.—This has been investigated principally by Strong. The intestine may show a diphtheritic false membrane, with often deep burrowing ulcers in the rectum and colon indistinguishable from those of amœbic dysentery. On microscopical examination the parasites can be found in the mucosa surrounded by a round-celled infiltration, and several observers have noted a marked eosinophilia of the intestinal wall.

Symptomatology.—The disease is insidious in its onset, being marked by attacks of diarrhœa, alternating with constipation and vomiting, with anorexia and at times the passage of blood and muco-pus in the motions. Œdema of the face and limbs may set in, and death result from exhaustion.

In our patient, a little native girl, there was rather high fever, with persistent diarrhœa, great wasting, and severe anæmia. No blood in the motions. The *Balantidia*, which were abundant, were associated with numerous *Trichomonata* and *Oicomonas;* moreover, the patient harboured various worms, ova of *Ancylostoma duodenale, Ascaris lumbricoides*, and *Trichuris trichiura* being present. Some of the symptoms may have been caused by these parasites.

Complications.—The parasite may enter the liver and form cysts. It may be associated with other parasites—*Amœbæ, Trichomonata, Oicomonata*, etc.

Treatment.—The symptomatic treatment laid down for amœbic dysentery may be tried, beginning with castor oil or salines, and followed by intestinal irrigations of tannic and boric acids or quinine. Ipecacuanha and emetine may be administered as described for amœbic dysentery. Large rectal injections of a solution of methylene blue (1 in 3,000), combined with the internal administration of the same drug in 1 or 2 grain doses in cachets or pills, may also be tried. Oil of chenopodium has been recommended.

Some authorities give Salvarsan by intravenous injection.

Prophylaxis.—It is not certain that the parasite found in the pig is the same as the human parasite, and, further, the method of infection being quite unknown, no useful remarks can be made with regard to prophylaxis.

(*f*) Spirochætic Dysentery.

This type of dysentery was first described by Le Dantec. It has not been generally accepted, as spirochætes may be found in cases of typical bacterial and amœbic dysentery and even in normal stools in which *Spiroschaudinnia eugyrata* Werner, *emendavit* Fantham, is commonly met with. It is very probable, however, in our opinion, that there may be pathogenic intestinal spirochætes capable of giving rise to dysenteric symptoms. In a case observed by one of us preparations from the muco-pus were teeming with spirochætes, while amœbæ and ciliates were absent, and the further bacteriological examination showed absence of dysentery bacilli. Emetine and serum treatment had no effect, and the patient made a very slow recovery.

Remarks.—A mistake not rarely made is to recognize as spirochætes the undulating forms of a germ found by Castellani in Ceylon, and described by him in 1910, under the term of *Spirillum* (*Vibrio, Vibriothrix, Spirobacillus*) *zeylanicum*, in the *Philippine Journal of Science*, vol. v., No. 2, Section B, 'Medical Sciences,' July, 1910.

The generic classification of this germ is most difficult, as it is extremely polymorphic, the same preparation showing bacillary, vibrionic, undulating forms.

At times coccus-like and also fairly large spherical bodies are seen and claviform swellings, and Castellani has recently created a new genus for it, *vibriothrix*, the name of the organism becoming, therefore, *Vibriothrix zeylanica* Castellani, 1910. This germ is found also in Europe, as recently shown by Castellani, Spagnuolo and Russo, by Taylor, Ghiron, and by Douglas.

Morphology.—The best way to see the characteristics of the germ is to make a preparation from the water of condensation of a glucose agar tube inoculated with it. In the same preparation forms so different in shape may be met with, that one might think one had to deal with two or more organisms living in symbiosis, but by plating and replating one never succeeds in separating the various forms. Long undulating forms may be present 20 to 40 microns in length, and also numerous short vibrio-like and bacillary forms, and in preparations from the pellicle which forms in certain media, curved filaments may be found with claviform swellings, and also globular small bodies.

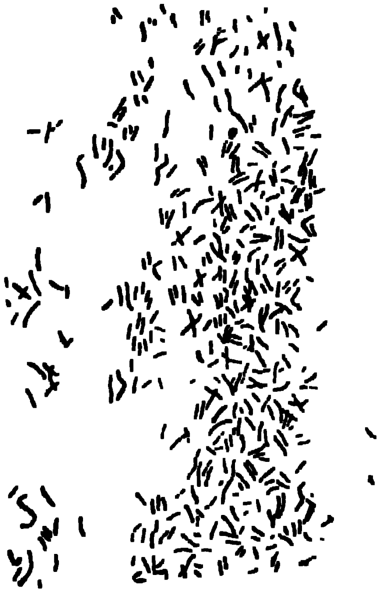

FIG. 764.—*Vibriothrix zeylanica* (CASTELLANI, 1910).
(Vibrio-like forms from a culture.)

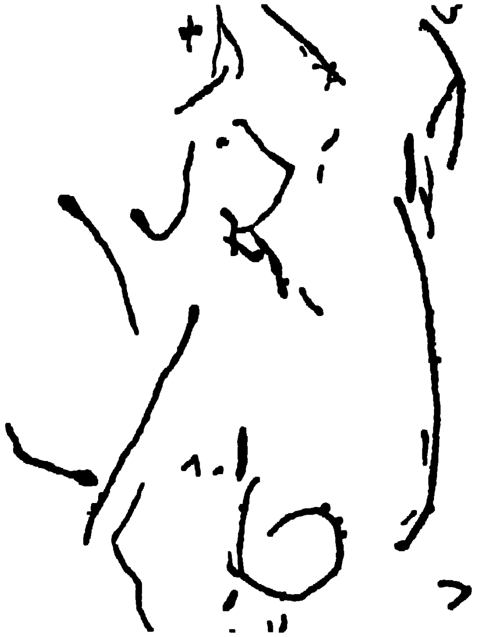

FIG. 765.—*Vibriothrix zeylanica* (CASTELLANI, 1910).
(Forms from the pellicle in a culture.)

The germ is easily stained by the usual aniline dyes. It is Gram-negative.

Motility.—The germ is motile.

Cultural and Biochemical Characters.—On MacConkey, Endo, and Drigalski-Conradi plates the colonies are similar to those of the germs of the typhoid dysentery group, the organism being a non-lactose fermenter. The micro-organism grows well on all the usual laboratory media, in the water of condensation of glucose agar tubes producing a rather characteristic pellicle. It often produces a pellicle also in broth and several sugar media. It produces neither acidity nor gas in any of the usual carbohydrates—lactose, glucose, levulose, galactose, saccharose, dulcite, mannite, maltose, dextrin, raffinose, arabinose, adonite, inulin; on the contrary, there is often production of alkalinity.

Most strains are non-pathogenic to rabbits and guinea-pigs when inoculated subcutaneously, but there are exceptions.

(g) Entoplasmic Dysentery.

In two cases of dysentery contracted apparently in Burma, Castellani observed peculiar protozoal bodies, while amœbæ and dysentery bacilli were absent. In fresh preparations one sees large rather elongated or oval bodies with one extremity, the one which in stained preparations appears mammillary, shaken, so to speak, by an extremely frequent vibrating movement, which makes one suspect the presence of flagella or cilia, or an undulating membrane. No such structures, however, can be detected either in fresh preparations or in slides stained with the usual methods, such as Giemsa, iron—hæmatoxylin, etc.

The protoplasm presents numerous roundish vacuoles, none of which is contractile. No distinct nucleus is evident in fresh preparations. The parasite does not emit true pseudopodia, but changes in the shape of the body take place.

Stained Preparations.—The typical forms have a peculiar flask-like appearance, but round forms are also found, the maximum diameter varying between 45 and 80 microns. In preparations stained with Leishman the protoplasm is stained blue and presents numerous non-stained roundish vacuoles regularly distributed all over. In certain individuals a large mass of chromatoid roundish coccoid granules are present, which represent, according to Mesnil, a diffuse nucleus. In one specimen the granules were bacillary in shape. In none of the bodies were flagella, cilia, or evidence of any undulating membrane seen by Castellani, Mesnil or any protozoologist to whom the specimens were submitted. It may be, of course, that such organs were of such extremely delicate nature that they required the use of special methods to put them in evidence.

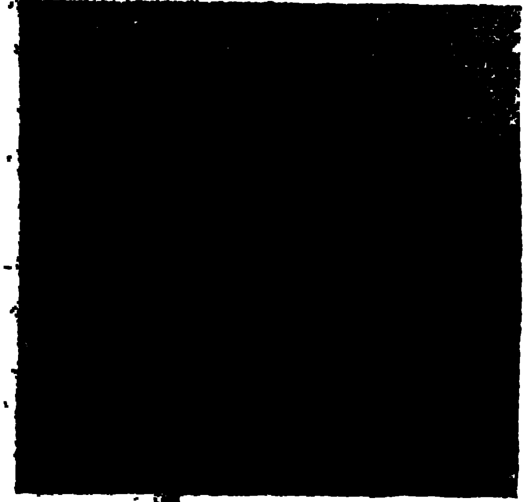

FIG. 766.—*Entoplasma castellani* PAUL, 1914.

Zoological Position of the Parasite.—It is impossible to classify this parasite, which, for convenience' sake, might be maintained in the temporary genus *Entoplasma*, until further researches render possible its proper classification. The suggestion has been made that these bodies are probably forms of *Chilomastix mesnili* Wenyon, but the size of the bodies apart from other characters is evidently against this hypothesis.

Symptomatology.—This was identical to what one sees in a case of amœbic or bacterial dysentery of medium gravity, the stools containing blood and mucus.

Treatment.—Salines were administered with good effects. Emetine was also given, but it is difficult to say whether it had any part in inducing the cure of the condition.

II. THE PLATYHELMINTHIC DYSENTERIES.

Fasciolopsis buski, *Schistosoma japonicum*, and *S. mansoni* cause dysenteric symptoms, which can only be diagnosed by the discovery of the eggs in the motions. The symptoms produced by the latter worms are described in detail in Chapter LXXIX. (p. 1864), while those of the former still require detailed investigation.

III. THE NEMATHELMINTHIC DYSENTERIES.

Nemathelminthic dysentery is due to the sclerostome (*Œsophagostomum brumpti* Railliet and Henry, 1905), immature females of which were found by Brumpt in cyst-like nodules in the cæcum and colon of a negro in West Africa. Similar symptoms are caused by *Œs. stephanostomum* var. *thomasi* Railliet and Henry, 1909, discovered in South America by Thomas (see p. 661).

IV. THE ARTHROPODIC DYSENTERIES.

We have already drawn attention to the fact that diarrhœas and dysenteries may be caused by the presence of species of the Chilopoda and Diplopoda, and by the larvæ of flies in the intestine, but these are rare, and are sufficiently described in Chapters XXVIII. and LXVII.

B. DYSENTERIES CAUSED BY BACTERIA:

The Bacillary Dysenteries.

Synonyms.—*French* : Dysenterie Bacillaire. *Italian* : Dissenteria Bacterica. *German* : Bacillenruhr.

Definition.—The bacillary dysenteries are acute or chronic, endemic or epidemic, specific intestinal disorders caused by several varieties of bacteria, which are disseminated largely by means of the fæcal matter of dysentery carriers, as well as by that of persons suffering from these disorders. From the sources of infection the germs are conveyed to food or drink by the agency of flies, dust, surface water, and by direct contact with any contaminated substance. Infection usually takes place by the consumption of contaminated food or drink, more rarely by direct contact with contaminated substances. In the body the micro-organisms cause a specific inflammation of the large, and occasionally also of the small, intestine, which is characterized by diarrhœa, usually accompanied by pain, tenesmus, and the passage of blood and mucus in the motions. More rarely the bacilli cause a general septicæmia.

History.—For years the theory of a bacterial causation for dysentery found many supporters, among whom may be mentioned Klebs, Prior, Ziegler, Hlava, Chantemesse, Widal, and Grigoriew, all of whom attempted to isolate a specific organism.

Maggiora, Laveran, Arnaud, and Escherich believed that the *Bacillus coli communis* was the true cause, while Celli described as the cause of the disease a bacillus fermenting glucose and clotting milk, which he called the *Bacillus coli dysentericus* ; but according to his more recent description some strains produce very little or no gas in glucose media, and may not clot milk, and closely resemble Flexner's bacillus.

During an epidemic in the province of Oita, in Japan, Ogata isolated a bacillus which liquefied gelatine, stained by Gram's method, and produced intestinal ulcers in guinea-pigs and cats, a discovery which was confirmed by Vivaldi of Padua, but not by other observers.

In the same year Calmette announced that the *Bacillus pyocyaneus* was a cause of dysentery in Cochin China, an observation since confirmed by Lartigan in the United States, Adami in Canada, and others, but not generally accepted.

The elucidation of the ætiology of bacillary dysentery is due to the investigations of Shiga in Japan and Kruse in Germany during the years 1898-1900. They described as the cause of the malady a short bacillus, not decolourized by Gram, not clotting milk, not producing gas in any sugar media. There was at first some difference of opinion as regards motility, but Kruse's statement that the bacillus was always non-motile has been proved to be correct. Kruse was also the first observer to state that there was more than one variety of dysenteric bacilli.

In 1900 Flexner reported that he had isolated a moderately motile bacillus from cases of dysentery in Manila identical with Shiga's bacillus, and producing a severe muco-hæmorrhagic diarrhœa in a human being who was the victim of an accidental laboratory infection. This bacillus was later demonstrated to be non-motile, and to differ in several respects from Shiga's bacillus, notably in fermenting certain sugar media, and could be distinguished therefrom by the different biological tests. These results have been frequently confirmed by observers in different parts of the world. Strong isolated a bacillus slightly different from that of Flexner, also from cases in Manila.

In 1903 Hiss and Russell separated a bacillus which closely resembles Flexner's bacillus, but fails to ferment maltose. This bacillus is often called the Y bacillus. In 1904 Castellani isolated a bacillus from cases in Ceylon which he named the 'paradysenteric bacillus,' and later he described the group of metadysentery bacilli. Several other germs have been described by various authorities, while Kruse, Flexner, Strong, Lucet, Conradi, and others have made a detailed study of the pathogenesis of the disease.

Climatology.—Bacillary dysentery is found all over the world, in cold, temperate, and warm climates, but especially in the latter. In temperate climates the germs probably cause a type of the infantile diarrhœas which are such potent factors in the infantile mortality of those regions, while they are also responsible for the endemic and epidemic cases so frequently met with in Europe and America.

In the tropics they are also extremely common, occurring more frequently at the end of the dry and the beginning of the wet seasons. In certain regions and at certain times the virulence of the complaint appears to be increased, the reason of which is not at present apparent. Probably it depends upon the greater possibility of infection, owing to the drinking-water being highly contaminated in warm weather, or perhaps to the presence of multitudes of flies. The agency of these or other factors has not been completely inquired into. Whatever the cause may be, it is well known that at times the disease may spread in epidemic form over larger or smaller areas. These epidemics may be institutional, urban, or rural, or they may attack a district, a country, or a continent. Thus, celebrated epidemics are known to have occurred in Europe in 1538, 1717-19, 1779-83, and 1834-36.

Dysentery is particularly prone to occur whenever sanitation is defective, and hence is found prevalent in lunatic asylums and in armies in times of active service, as is clearly shown by the present war; and this factor appears to be more potent than any climatological cause, and, indeed, may be the principal reason why the disease is so prevalent in the tropics, though the high atmospheric temperature of these regions must assist the growth of the organisms.

Ætiology.—Bacillary dysentery is brought about by a group of closely allied bacilli which may be separated into several principal types according to their fermentative action on glucose, mannite, maltose, saccharose, lactose.

I. *Shiga-Kruse Type.*—Glucose fermented (acid only); mannite, maltose, saccharose, lactose not fermented. Agglutinated only by homologous serum. Not agglutinated by normal horse serum. Very toxic to rabbits.

II. *Flexner Type.*—Glucose, mannite, maltose fermented (acid only); saccharose not fermented, but there are exceptions; lactose not fermented. Agglutinated by homologous serum and Y serum, and not unfrequently by Shiga serum and, as shown by M. Nicolle, normal horse serum. Non-toxic to the rabbits.

III. *Strong Type.*—Glucose, mannite, and saccharose fermented (acid only); maltose not fermented. Agglutinated by homologous serum only. Most authorities consider it non-toxic, but the original Strong strain was very toxic to rabbits.

IV. *Hiss and Russell Type.*- Glucose and mannite fermented (acid only); maltose, saccharose, lactose not fermented. Agglutinated by homologous and Flexner serums, at times by Shiga serum and normal horse serum.

V. *Metadysentery (Castellani) Type.*—Differs from all above groups in fermenting (slowly and acidity only) lactose in addition to glucose. Well agglutinated by homologous serum; not agglutinated by Flexner and Shiga serum. Non-toxic to rabbits.

For more details on bacteria of the dysentery group the reader is referred to Chapter XXXVI., p. 936. Less important types are Rüffer and Willmore's *Bacillus El Tor* No. 1, Baerthlein's *Bacillus dysenteriæ*, Shiga's *B. dysenteriæ Tokio*, Castellani's *Bacillus paradysentericus*, etc.

Hiss divides the dysentery bacilli into four principal groups:—

Group 1: Ferments glucose only (Shiga-Kruse bacillus).

Group 2: Ferments glucose and mannite (*Bacillus Y*).

Group 3: Ferments glucose, mannite, and saccharose (Flexner - Manila bacillus).

Group 4: Ferments glucose, mannite, saccharose, maltose, and dextrine (Harris's bacillus, Wollstein's bacillus).

Leitz, Kruse, and Shiga have called attention to the fact that while the fermentation of mannite is a reliable means of differentiation, not so much importance can be given to the fermentation of maltose, saccharose, and dextrine.

Lehman and Neumann give the following classification:—

1. Shiga-Kruse: No fermentation of mannite, maltose, saccharose.
2. Flexner: Ferments mannite and maltose.
3. Strong: Ferments mannite and saccharose.
4. B.Y.: Ferments mannite; has no action on maltose and saccharose.

Bahr has noted that the various strains may vary their fermentative character when passing through flies.

Under the term *B. pseudo-dysentericus*, Kruse described a non-lactose fermenting bacillus which is the cause of many outbreaks of asylum-dysentery in Germany. Later he used the term 'pseudo-dysentery' to denote every variety of dysentery caused by bacilli other than those of the Shiga-Kruse type.

Celli's *B. coli dysentericus*, according to the original description, is motile, clots milk, and produces gas in some sugar media, and therefore cannot be considered to belong to the dysentery group. According, however, to more recent descriptions by De Blasi and others, some strains of the *B. coli dysentericus* may not produce gas, and may not clot milk, and closely resemble Flexner's bacillus.

The true dysenteric bacilli may be differentiated from one another by their varying fermentative actions upon carbohydrates, by agglutination, Pfeiffer's reaction, and Castellani's absorption method. A table showing the characters of the more important dysentery germs as well as other intestinal bacteria will be found in Chapter XXXVI., p. 944. We wish to emphasise, however, the fact that the biological reactions of the bacilli are much more reliable than the fermentative changes.

The dysenteric bacilli are distributed mainly by the fæces of persons suffering from the disease, but there are also 'dysentery carriers' in the true sense of the word, who are perhaps not merely an important source of infection, but possibly *the important factor* in the dissemination of dysentery.

Strong and Musgrave have proved that infection takes place by the mouth by feeding a man with pure cultures of the dysentery bacillus, which quickly produced an attack of dysentery, characterized by motions containing blood and mucus, from which the typical bacilli were grown.

The most prevalent method of infection is direct contact with a patient or a carrier, or with articles or more especially food contaminated by them. The bacilli are conveyed from fæcal matter to the mouth by the contamination of food or drink, or the utensils for preparing or serving the same. This method of infection is probably common in hospitals and asylums, cooks and all persons engaged in handling food being possible disseminators. Another method of dissemination would appear to be the dust, especially in places with badly polluted soils. Flies, as has been experimentally demonstrated by one of us, are capable of carrying the bacilli, and are therefore probably a prolific source of infection in tropical countries. Luckily the water-supply is very rarely infected. With regard to lower animals, Kruse and Bowman have recorded spontaneous bacillary dysentery in monkeys, due to bacilli of the Flexner group, and Messerschmidt has found a bacillus of Type Y in the fæces of apparently healthy rabbits, so that there may be a possibility that lower animals are of importance in the spread of the disease.

It would, however, appear that the bacilli are capable of living in the alimentary canal without causing the symptoms of the disease until the vitality of the host is lowered by some agency, such as a chill, an attack of diarrhœa, or some intercurrent disorder, when they are capable of producing their ill-effects.

This carrier problem in the ætiology of dysentery is of great importance, and though as yet it has never been *conclusively* proved that an outbreak has been due to a carrier, still it is known that the bacilli can be excreted in an intermittent manner by people suffering from mild relapses. The dysentery carriers are classified into—(1) healthy, (2) precocious, (3) convalescent, (4) relapsing, and (5) chronic carriers. The healthy carrier is rare, but May has found 22 out of 573 persons examined during an epidemic. The precocious are believed to be very rare. The convalescent and relapsing carriers are well known, of which the latter are of the greatest importance in spreading the disease. The chronic carrier excretes but few bacilli, but may be of importance in the spread of the disease. With regard to the geographical distribution of the principal forms of bacilli, it may be stated that practically all of them seem to have a cosmopolitan distribution.

Ætiological Classification of Bacterial Dysenteries.—An ætiological classification of bacterial dysenteries has been suggested as follows:—

I. Due to *B. dysenteriæ* Shiga-Kruse—*Bacterial dysentery sensu stricto.*

II. Due to mannite fermenting dysentery bacilli (Flexner, Hiss and Russell, Strong)—*Paradysentery.*

III. Due to germs having the general character of the dysentery bacilli; but slowly fermenting (acidity only) lactose and not agglutinated by Shiga-Kruse, and paradysenteric serums—*Metadysentery.*

Pathology. The bacilli taken into the body with food and drink pass to the intestine, in which they grow and multiply, and along the whole length of which they can be found. The researches of Flexner and Sweet have proved that the bacilli can abound in the small intestine, where no pathological lesion may be found. In the bowel they give rise to the toxins, of which two are known—one which acts upon the lower bowel, and the other on the nervous system. Both these toxins are absorbed into the blood, but the first, being excreted by the large bowel, causes the lesions well known to be associated with dysentery, and explains the localization of these lesions. In the process of excretion this toxin first causes an exudation of lymph into the submucosa, and later into the mucosa. This lymph coagulates, and is invaded by a cellular exudate, and in due course the glands and the tissue of the mucosa and the muscularis mucosæ are destroyed by coagulative necrosis, with thrombosis of the vessels. This fibrinous or diphtheroid membrane is at first most marked on the summits of the ridges, and may not be found at the bottom between the ridges. It contains large numbers of micro-organisms of varying characters, while the depths of the submucosa may reveal accumulations of leucocytes, and the peritoneal coat may be œdematous. The micro-organisms destroy the fibrinous false membrane, which may separate off in flakes, thus causing ulcers, which are at first superficial, but later become deep and extensive. After treatment these ulcers heal with the formation of connective tissue, thus producing a scar in the mucous membrane, which in due course becomes pigmented from the sulphuretted hydrogen of the bowel acting on the iron of the blood. The other toxin may attack the nervous system, causing peripheral neuritis.

Very rarely do the bacilli enter the blood stream, and cause true septicæmia, though such cases have been recorded by Rosenthal and Markwald, the latter observer stating that he found the bacilli in the blood and intestinal contents of a fœtus which had been prematurely expelled from the uterus of a mother who was suffering from bacillary dysentery. Darling has actually grown the bacillus from the blood of cases of bacterial dysentery. Occasionally the bacilli affect the joints and very rarely the conjunctiva.

Morbid Anatomy.—On opening the abdomen, the peritoneum is found in general to be normal, but the bloodvessels of the large bowel are seen to be injected, and the mesocolons may be infiltrated with lymph, or firm and fibrinous. There may be adhesions of the sigmoid colon to the omentum, pelvis, bladder, or small intestines, while the splenic flexure may be adherent to the spleen and surrounding parts, and the hepatic lexure to the liver. The cæcum may show adhesions to the omentum, and more rarely there may be pericæcal abscess. Signs of a general peritonitis may be met with, and will generally be associated with a gangrenous or perforated condition of the intestine.

The small bowel is usually normal, but may be hyperæmic or, much more rarely, ecchymotic. The walls of the large intestine are usually considerably thickened and hyperæmic, and may at times be found to be gangrenous along a great or lesser extent of their course. On opening the large bowel, the mucosa will be seen to be covered with a coagulated exudate in the form of a false membrane, which is more evident on the summits of the folds, and is especially well marked in the sigmoid colon, the cæcum, and the ampulla of the rectum. Around the areas covered by the false membrane the mucosa is seen to be hyperæmic and œdematous. As a rule, numerous ulcers are also to be seen, with clean surfaces, elevated edges, and a base formed by the submucosa. These ulcers may be very extensive, leading to the separation of large sloughs, or may extend deeply into the coats of the bowel, causing perforation and peritonitis, or in less serious cases induce the exudation of much lymph into the peritoneum coat, which subsequently causes adhesions.

In post-mortem examinations of cases which have died from some other complaint it is not unusual to find the intestines matted together in the pelvis, the omentum adherent to the colon, and the colon to the bladder, etc. On opening such a colon it will be found scarred by old dark-coloured cicatrices, indicating the position of the healed ulcers of a previous dysentery. More rarely the cicatrization may have proceeded to such an extent as to cause narrowing of the lumen of the gut, and still more rarely may the process lead to abscess formation in the adherent omentum, the pus of this abscess slowly working its way into the anterior abdominal wall, and so to the exterior. The cæcum and other parts of the bowel may show polypi protruding from the mucous membrane, a condition often called 'colitis polyposa.'

In the epidemic diarrhœa of infants, the lesions which may be found are classifiable into hyperplasia of the agminated and solitary glands, superficial ulcers, lesions resembling those described above, or invisible lesions.

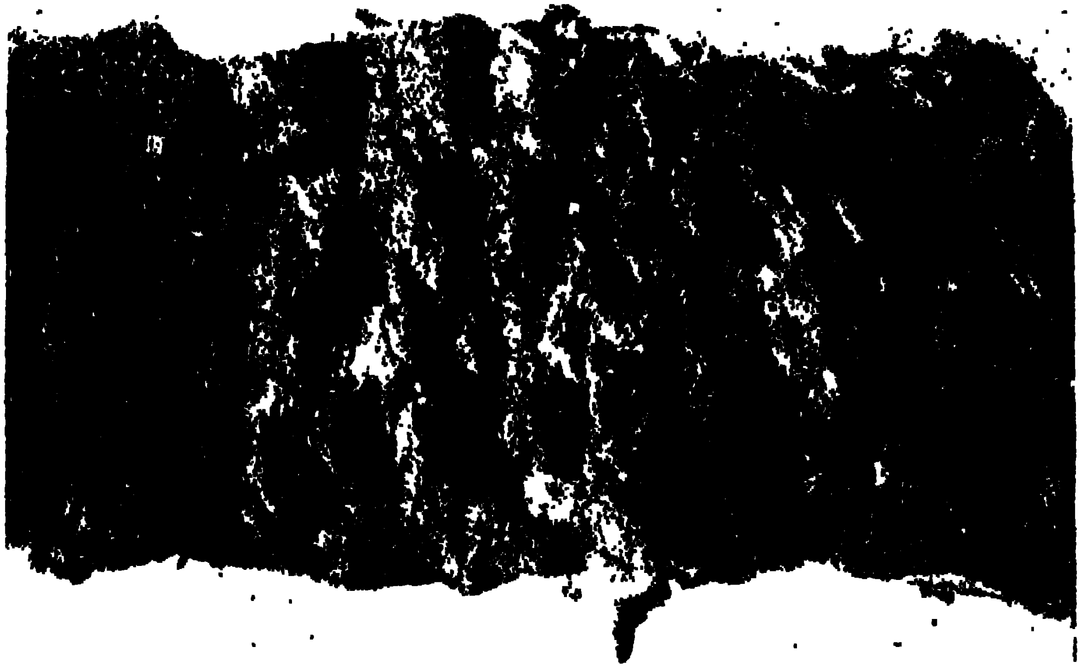

FIG. 767.—THE COLON IN A CASE OF BACILLARY DYSENTERY.

Microscopically, there is at first an exudation of fluid containing but few cells into the submucosa, while the mucosa is congested, but the glands are seen to be quite normal. A little later the exudate into the submucosa is seen to have formed fibrin, and the vessels of this coat are noted to be dilated, to contain numerous polymorphonuclear leucocytes, which may be seen undergoing diapedesis into the surrounding tissue. In this stage the exudate has also affected the mucosa, the glands and tissue of which may be seen to be undergoing coagulative necrosis. In a still later stage nothing is to be seen of the mucosa, and in bad cases of the submucosa, except fibrinous exudate, mixed with cells and blood-vessels. Often, however, the submucosa shows dense collections of leucocytes. Where ulcers occur, the amount of exudate covering the muscular coat may be thin, while in other places it may be thick. The peritoneum is also generally infiltrated by a coagulated exudate.

Symptomatology.—The different appearances presented by the bacillary dysenteries may be grouped into:—

1. The acute type.
2. The gangrenous type.
3. The entero-dysenteric type.
4. Choleraic dysentery.
5. Chronic dysentery.
6. Dysenteric diarrhœa.
7. Dysenteric infantile diarrhœa.

1. *Acute Bacterial Dysentery.* -The incubation varies from twenty-four hours to three or four days, and is not well known in natural infections. Usually after an incubation of a few days, during which the patient may not feel quite well, and may complain of constipation or diarrhœa, with loss of appetite and malaise, the disease begins with an attack of pain in the lower part of the abdomen, and an urgent desire to defæcate, which results in the passage of perhaps an ordinary formed fæculent motion, which temporarily relieves the pain. Soon, however, another attack of pain is felt, generally in the region of the umbilicus, from which it radiates to any part of the large intestine, and this is again associated with a desire to defæcate and the passage of a motion which is composed of fæcal matter, but may now be soft. The pain increases, and the desire to defæcate becomes more and more frequent, until almost constantly present, while any nourishment, however bland and unirritating, at once produces a desire to defæcate. After a time the patient sits almost continuously upon the commode, straining violently, and passing at first motions of fæculent matter mixed with blood and mucus, and then blood and mucus mixed with a little fæculent matter, and finally nothing but a little blood and mucus. As a result of the straining and the passage of numerous motions, the anus becomes inflamed and very painful, and prolapse of the bowel is not uncommon, and adds greatly to the distress of the patient. The urine diminishes in quantity, and therefore may show an increased quantity of urea, and at times may contain a trace of albumen. Pain is often complained of in the region of the bladder during and after straining at the commode. In slight cases the number of motions may be only about one every hour, but in more severe cases they number from fifty upwards, until they are passed almost continuously. This constant pain and desire to defæcate naturally weakens and exhausts the patient very quickly, for it prevents sleep and rest.

In ordinary cases the tongue is moist and coated with a white fur, and usually the patient is thirsty, but not markedly so, except in bad cases. Nausea is often present, and there is no desire for food, which is badly digested. There is often epigastric pain. Vomiting occurs, but is relatively unusual in cases which are taken in hand early and properly treated. The abdomen soon becomes sunken and tender, especially along the course of the large bowel, but this tenderness may be restricted to certain areas only of that bowel. On careful palpation the thickened bowel may at times be felt, but usually it is too tender to allow such manipulation. With the numerous motions, it may be imagined that constipation would not occur; but this is not so, for the disease may be limited to the lower bowel, and as it is the involvement of the rectum which causes the tenesmus and constant desire to defæcate, fæces may be accumulating in the higher region of the large bowel —a condition which may be recognized by the distension. Shiga, indeed, describes an ascending variety of acute dysentery, which, beginning in the rectum, spreads upwards along the large bowel, as well as a descending variety, which usually starts in the small intestine. The typical motions are composed of blood and mucus only, but in bad cases they may consist of a reddish albuminous fluid containing white shreds. The typical dysenteric motions have no fæcal smell, and microscopically show numerous micro-organisms, leucocytes, and red cells, and epithelial débris and cells. Usually there is some fever, ranging from 99° to 103° F. The pulse is quickened, and in bad cases may be not merely rapid, but irregular, when the heart will be found to be dilated, and perhaps hæmic murmurs may be heard; but these symptoms are unusual, except in grave cases. The blood usually shows a diminution in the red cells, and a slight polymorphonuclear leucocytosis. The lungs are usually normal. Delirium is unusual.

If the patient is to die, the motions assume the serous character mentioned above, the pulse becomes rapid and irregular, the temperature drops to subnormal, the motions diminish in number, hiccough appears, and exhaustion ushers in death generally during the second or third week.

If the patient is to recover, the motions become more fæculent, and the blood and mucus generally disappear, while the pain and tenesmus subside, the pulse returns to normal, the tongue cleans, and convalescence begins about the end of one week in mild, or of one month in more severe cases.

2. *Gangrenous Dysentery.*—This most severe type of the disease may begin insidiously with some slight fæculent diarrhœa, which may not attract attention until suddenly the patient becomes collapsed and dies within a few hours without the passage of the typical motions. Thus a prisoner may stand in the dock throughout the whole day, and then die in the night from gangrenous dysentery, while his sudden death may awake suspicions of suicide.

The more usual history is that, during an attack of acute dysentery, the abdominal pain and tenesmus become very severe, while the motions alter their characters, becoming exceedingly offensive, and containing gangrenous sloughs composed of the mucosa and the submucosa. These sloughs may be small or large, and even at times may be tubular. The motions are now exceedingly numerous, and sometimes hæmorrhage *per anum* may take place. The patient becomes extremely exhausted, the pulse small and frequent, the temperature falls to subnormal, and the extremities become cold up to the knees and elbows, while the motions are passed involuntarily, and death takes place in some two or three days from exhaustion. Recovery from an attack of gangrenous dysentery is extremely unusual, but when it does occur the pulse slows, the temperature rises, the motions become fæculent again, and the urine, which has been suppressed, reappears.

3. *Entero-Dysentery*.- This variety begins with one or more rigors, and a rise of temperature to 103° F. or more. The temperature keeps high, assuming either a continuous or a high remittent type, and is associated with a dry tongue, and a mouth covered with sordes, fœtid breath, headache, malaise, pains in various parts of the body, marked epigastric disturbance, and occasionally with ecchymoses under the skin in various parts of the body. The characteristic signs of abdominal pain and tenesmus are absent, and the motions, though containing blood and mucus, are mixed with considerable quantities of fæculent matter. The mind is clouded, the patient becoming very stupid, sleepless, and at times delirious. Abscesses may now appear in varying parts of the body, but especially in the parotid or the ischio-rectal fossæ, while carbuncles, bedsores, and peritonitis may also occur. Death usually ensues after a few days' illness from exhaustion, toxæmia, or hyperpyrexia.

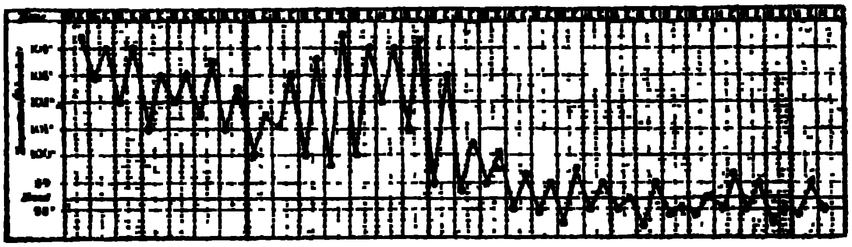

FIG. 768.—TEMPERATURE CHART OF A CASE OF BACILLARY DYSENTERY, SHOWING THE EFFECT OF SERUM TREATMENT.

Chart by Archibald.

4. *Choleraic Dysentery*. Castellani called attention some years ago in the tropics, and again recently in various war zones, to a type of dysentery or serous diarrhœa which is often mistaken for cholera. The onset is sudden, with rice-water-like or serous motions; there may be vomiting, and the condition of the patient becomes rapidly very grave. In most cases, however, a motion is passed now and then tinged with blood, and this clears the diagnosis.

5. *Chronic Bacterial Dysentery*.—Chronic dysentery appears after an attack of acute dysentery which has apparently been cured, but in which, after a period of quiescence, diarrhœa appears. About five or six motions, composed of watery, evil-smelling, fæcu-

lent matter, are passed per diem, and may at times contain blood and mucus, or simply mucus. After a time these symptoms disappear, and the motions become normal, or there may be slight constipation. In due course, however, the diarrhœa returns, and these exacerbations recur for months and years, and seriously affect the patient's general health. The appetite becomes bad; the tongue red and smooth, or flabby and coated; digestion is impaired, and fermentative changes cause the bowels to be distended with gas; while hæmorrhage, slight or severe, may take place from the nose or under the skin. Profuse sweats may occur at night, and tend to exhaust the patient. Recovery may take place spontaneously, or after treatment, or the diarrhœa, continuing fitfully, may gradually wear out the patient, who may die of exhaustion or some intercurrent disease. Some authorities believe that chronic dysentery may become sprue. We do not agree with them, although, of course, sprue may develop in a case of chronic dysentery.

6. *Dysenteric Diarrhœa.*- The term 'dysenteric diarrhœa' may be applied to the non-bloody diarrhœa of chronic dysentery, and to those cases of diarrhœa which occur during an epidemic of dysentery, and in which the bacillus is either proved to be present in the motions, or the patient's blood agglutinates in high dilution one of the dysenteric bacilli. The attack may in no way differ from an ordinary attack of diarrhœa due to other causes, but is apt to recur and to turn into chronic dysentery.

7. *Dysenteric Infantile Diarrhœa.* -Diarrhœa is an extremely common disease among infants in the tropics, but has not yet received the attention which it has in the United States, in Europe, and in Japan, where it is called 'ekiri.' It is believed to be due to Flexner's bacillus, or more rarely to Shiga-Kruse's bacillus; while the symptoms resemble entero-dysentery, being characterized by beginning with vomiting, and a rise of temperature from 103° to 104° F., a dry mouth, coated tongue, distended and tender abdomen, and the passage of motions containing fæculent matter, often green in colour, generally mixed with blood and mucus. The fever is of the remittent type, and as the disease progresses the child wastes, and may become convulsed or comatose and die, or may live for weeks, suffering from repeated attacks of diarrhœa, and finally die from exhaustion. If recovery is to take place, the temperature declines and the diarrhœa ceases, but the child is left in a pale and emaciated condition, from which it takes months to recover.

Complications.—Peripheral neuritis is not uncommonly met with, generally in a mild form, and often confined to one nerve. Arthritis and polyarthritis are also not uncommon, while inflammation of the tendon-sheaths may also take place. In entero-dysentery parotid buboes are not uncommon, while abscesses in other parts of the body and peritonitis may develop. In gangrenous dysentery hæmorrhage may be a serious complication. Typhoid fever may occur at the same time as a dysenteric attack, and is a serious complication. We have met with several cases of appenditicis developing in people convalescent from dysentery. Conjunctivitis and iritis have been recorded.

Sequelæ.—One of the most important sequels of dysentery, to which Cantlie has drawn attention, is stenosis of the large bowel, and more particularly of the sigmoid flexure, due to cicatricial contraction of the healing ulcers. The symptoms are the onset of an insidious constipation, associated in due course with a sensation of distension in the abdomen, loss of appetite, and nausea. The constipation is apt to alternate with attacks of diarrhœa. In due course the constipation becomes severe, and is accompanied with recurrent attacks of colic, in which the pain may be localized or radiating, and sooner or later vomiting occurs. On inspecting the abdomen a swollen region may be observed, and the attacks of colic may be seen to be associated with visible peristaltic movements, while more or less meteorism occurs. Succussion sounds may be heard over the dilated bowel. This condition is serious, and must be energetically treated.

According to some authors, 'sprue' is a sequel to dysentery, and we have, in fact, seen several cases of sprue developing in patients who have been suffering from chronic dysentery. We believe, however, the two diseases to be of different ætiology.

Diagnosis.—It may be of advantage to say a few words, first, on the diagnosis of dysentery in general. In presence of a patient suffering from abdominal pains, with frequent stools containing blood and mucus, the practitioner is, as a rule, justified in making the generic diagnosis 'dysentery.'

Next the specific diagnosis must be made—viz., what type of dysentery is the patient suffering from. For practical purposes it is sufficient in the enormous majority of cases to keep in mind the following types: amœbic dysentery, ciliar dysentery, bacterial dysentery. A particle of the muco-pus, immediately after evacuation, should be examined microscopically, and this examination can be carried out with great advantage at the bedside by means of a portable microscope. If the microscopical examination shows presence of amœbæ of the histolytica type, especially if containing red blood cells, the diagnosis will be *amœbic dysentery*. If amœbæ of the histolytica type are absent, and ciliates of the balantidium type are present, the diagnosis will be *ciliar dysentery*. If on prolonged and repeated examination, amœbæ and ciliates are absent, the diagnosis of probability will be *bacterial dysentery*. A probable diagnosis of bacterial dysentery can be made also by the practitioner who is not in position to carry out microscopical examinations, if emetine does not make the dysenteric symptoms disappear within three days.

The diagnosis of bacillary dysentery has to be made with special reference to pseudo-dysentery and amœbic dysentery, especially when there is blood and mucus in the motions, and from the various forms of diarrhœa when these signs are absent.

With regard to pseudo-dysentery, cancer and syphilis of the rectum and inflamed hæmorrhoids may give rise to tenesmus and the passage of blood and mucus, but can be differentiated by the history and by an examination of the rectum. Cancer of the colon and intussusception may also cause the passage of blood, with or without mucus and with or without tenesmus, but the history and a careful abdominal examination, together with the discovery of a localized swelling, should serve to distinguish these affections. Parametritis on the left side may cause diarrhœa, and more rarely the passage of blood and mucus, but the absence of tenesmus, the presence of pain more at the side of the uterus than in the sigmoid colon, should indicate the necessity of an examination *per vaginam* or *per rectum*, when the nature of the case will be cleared up. A careful examination of the fæces should exclude such causes as fish-bones injuring the rectum. Mercurial poisoning can be distinguished by the history, the presence of salivation, etc. The diagnosis from amœbic, balantidic, and the other dysenteries of animal origin can only be made by the careful microscopical examination of the fæces, when the absence of these parasites will be made certain. The absence in dysenteric stools of Charcot-Leyden crystals and presence of very abundant cellular exudate with macrophages and preponderance of polymorphonuclears points to the condition being bacterial rather than amœbic.

Positive diagnosis can, however, only be made by a bacteriological examination of the fæces and the determination of the specific bacillus. Agglutination tests with the patient's blood are not of much use in acute cases, as agglutinins are not present in the blood the first few days of the disease.

For the bacteriological diagnosis a shred of mucus or pus is smeared over a plate of MacConkie's bile-salt-lactose-neutral-red agar, by means of a bent glass rod or Kruse's platinum pencil.

Two more plates of the same medium are prepared in a similar manner without recharging the rod or pencil.

Any white colonies which develop are further investigated as to their sugar reactions, and by using the agglutination and absorption methods.

The following method will be found useful: - Twenty white colonies are selected; in this way we discard all lactose rapid fermenters. From each colony one glucose peptone water (or glucose agar) and a litmus milk are inoculated. After sixteen to twenty-four hours at 35° C. to 37 C. the glucose and milk tubes so inoculated are examined: all the strains which have produced gas or clotted milk are discarded. In this way we discard all germs of the genus Salmonella, Lankoides (p. 938), etc., and we retain only the strains which do not produce gas in glucose and do not clot milk. If a germ does not produce gas in glucose, as a rule it does not produce it in any other carbohydrate, and therefore we may say that we are left with strains which do not produce gas in any sugar and do not rapidly clot milk, and which, therefore, if they are bacilli, must belong to one of the following groups:— (*a*) Eberthus (p. 930), (*b*) Alcaligenes (p. 930), (*c*) Vibriothrix (p. 1068), (*d*) dysentery-metalkaligenes group *sensu lato*. From the glucose tubes hanging-drops are made; all germs which are not bacilli are discarded, and similarly all motile germs. In this way we shall retain only germs which are non-motile bacilli, which do not produce gas in any sugar, and do not clot milk—bacilli, therefore, which belong to the dysentery (glucose acid) and metalkaligenes group (glucose not acid). Those which ferment glucose (acidity only) are further investigated, and agglutination reactions are carried out, using Shiga, Flexner, and other dysenteric sera.

At times it will be found of advantage to use the so-called *Castellani's contemporary gas-agglutination test*. Tubes of glucose peptone water with Durham's fermentation small tubes are prepared, and two or three drops of a mixed serum, Shiga-Flexner, Hiss, etc., added. Twenty white colonies are inoculated in twenty such tubes. If any of these tubes, after twelve hours in the incubator, shows absence of gas and presence of agglutination, a diagnosis of bacterial dysentery can be made, though not of what variety of bacterial dysentery. It must be remembered also that there are rare strains of dysenteric bacilli which are not agglutinated by any of the usual antidysentery sera.

We wish to emphasize the fact that simple agglutination is not sufficient to diagnose that a certain bacillus is a dysentery bacillus. As shown by Levi della Vida, by one of us, and other observers, it is not at all rare to isolate from dysentery patients bacilli which are extremely well agglutinated, say, by Shiga serum, but which produce gas in glucose. Notwithstanding the opinion of a few authorities, such germs cannot be considered to be true dysentery bacilli, they are nosoparasites or secondary invaders. Hence the importance of carrying out fermentation tests in addition to serological tests.

To the bacteriological diagnosis of bacterial dysentery may be applied also *Castellani's polyserum method* as used for the diagnosis of cholera. A large number of the white colonies from MacConkey plates are inoculated in a tube of peptone water containing a few drops of lactose non-fermenters agglutinating polyserum (excepting the dysentery group) In theory all non-lactose fermenters, apart from the dysentery bacilli, will be agglutinated, while the dysentery bacilli will grow diffusely; in practice, however, many difficulties are met with owing to the great difficulty in producing an efficient polyserum.

Finally, we wish to call attention to the necessity of carrying out the bacteriological examination for dysentery on stools absolutely fresh, as soon as evacuated, plates being made at the bedside and then sent to the laboratory. If this precaution is not carried out, a very large number of cases will give negative results.

Prognosis.—In the milder forms of acute dysentery, the prognosis is good, recovery being the rule, but the death-rate of severe acute dysentery is high, while the prognosis in gangrenous dysentery is very bad. As an average, the mortality of the various forms may perhaps range from 12 to 25 per cent., for there is no doubt that in Ceylon and other tropical countries dysentery is a more potent factor in the death-rate than malaria, though the latter may cause more illness.

The site of the disease is also a factor in determining the prognosis, being as a rule better if it is situate low down, and worse if high up in the bowel. According to Kruse, Shiga, Duval, Dopter, and our own experience, early serum treatment lessens the mortality and therefore improves the prognosis.

As regards age and sex, the prognosis is better for adults than for children, and for men than for women. The European or new-comer into the tropics suffers more severely than the native resident race, but this racial difference is merely relative.

Treatment.—In all cases, however mild, the patient should be kept at rest in bed, and the urine-bottle and bed-pan must be used. The latter should preferably be slightly warmed before being used, especially in cool climates. Damp cotton-wool should be substituted for sanitary paper, in order to prevent irritation of the region of the anus.

All motions should be disinfected, after having been seen by the physician, with Jeyes' fluid or carbolic acid, and they should also be protected from flies. It is, however, most necessary that the motions should be saved for the physician to see, because they are extremely important in judging the progress of the case.

In very mild cases the bowels should be cleansed by an initial dose of one tablespoonful of castor oil, which may be administered in neat brandy, with or without a few drops of liquor opii sedativus or tincture of opium, and this should be followed a few hours later by the administration of astringents, such as bismuth salicylate 5 grains, and salol 5 grains, made into cachets, and taken every two or four hours at first, and less frequently when the character of the motions improves. In these mild cases tenesmus rarely requires any special treatment, and rectal injections are well borne, and may be administered twice daily, though in most cases they are unnecessary. These injections should consist of either boric acid (1 in 100), which is probably the best, salicylic acid (1 in 500), tannic acid (1 in 500), normal saline solution, or borax and bicarbonate of soda (5 grains of each to the ounce). In administering these enemata, the patient should lie on the left side, with the buttocks elevated on a pillow and the head placed low. A soft rectal tube should be smeared with vaseline and passed as high up the bowel as possible. Two pints of the enema are now run in by gravity from a glass irrigation vessel, and should be warmed to a temperature of about 99° to 100° F. The enema should be retained as long as possible. This treatment, with an appropriate diet, soon gives relief, the pain disappearing, the motions becoming fæculent. During convalescence a tonic of hydrochloric acid, cinchona bark, and gentian is found to be very serviceable.

In **severe cases** the serum treatment should be used as soon as possible, though at times it is useful to precede it with a dose of castor oil and associate to it the saline treatment. Kruse's serum, Shiga's serum, the Lister Institute serum (Todd), and that of the Pasteur Institute (Vaillard and Dopter), are all good. A polyvalent serum, such as that of Shiga, is preferable in those cases in which a complete ætiological diagnosis of the malady cannot be made.

The serum, in our experience, should be given in large doses; thus that from the Pasteur Institute and the Lister Institute should be given in 20 c.c. to 40 c.c. doses twice daily, and in very severe cases four times daily. The injection should be made under the skin of the abdomen or flank, using the ordinary aseptic precautions. These injections, as a rule, need not be continued after the second or third day. They may be followed by urticarial-like eruptions and pains in the joints. Calcium chloride or, better, calcium lactate in doses of gr. x. may be administered if these symptoms are severe three or four times daily. When the blood and mucus have disappeared from the stools, salol (gr. x. every four hours) or the ordinary astringents, such as bismuth subnitrate, or tannalbin (gr. x. to xv. every two hours), should be prescribed.

Our rules for the administration of the polyvalent serum are:—

I. In mild cases inject one dose of 20 c.c.

II. In cases of medium severity inject two doses daily of 20 c.c. for two days.

III. In severe cases inject 40 c.c. twice or thrice a day for two or three or four consecutive days.

As a rule the serum treatment should not be continued for more than four or five days, and it should not be repeated later on, or symptoms of anaphylaxis may develop.

The serum has often a marked effect upon the disease, hastening the cure, ameliorating the symptoms, and reducing the mortality, but it must be admitted that in certain cases it has practically no action whatever.

When the serum treatment cannot be carried out, the *saline treatment* is, in our experience, the most useful. Two drachms of magnesium sulphate and 2 drachms of sodium sulphate, dissolved in an ounce of water, chloroform water, or peppermint water, should be administered, and then 1 drachm of each should be given every two hours, or half doses every hour, until the motions become fæculent.

There is generally considerable pain in these more acute cases, and therefore a fomentation sprinkled with laudanum should be applied to the abdomen, and the tenesmus should be relieved by suppositories of morphia or of cocaine. If these remedies fail, then hypodermic injections of morphia or opium (gr. ½) by the mouth must be given, for it is a most important factor in the treatment that the patient should not suffer more than can possibly be avoided from this distressing symptom. If prolapse of the anus or rectum occurs, it is important that this should be reduced and relieved by an astringent ointment, such as hazeline or gall and opium.

Rectal injections may be given, as described above, but in sensitive cases it is as well to pass in a second tube alongside the enema-tube, so that, instead of the inflamed bowel being distended by the injection, it may be simply washed by the irrigation of the boric lotion.

During the treatment of the severe acute forms a great danger is to stop the saline treatment too quickly, and to allow constipation to occur, by which is meant that, though the patient may be having fifty to a hundred motions per diem, still fæculent matter is being retained. On the other hand, there is danger in continuing the saline treatment too long, for in our experience this should be stopped on the third day if there is no improvement, and also when the motions become serous.

After the acute stage is over it may be found useful to employ some astringent drugs, such as tannalbin, 15 grains every two hours, or large doses of bismuth subnitrate (gr. xv. to xxx., with or without salol (gr. v. to x.), every two hours, in cachets or emulsion, and an enema of boracic or tannic acid (½ to 1 per cent.) *per rectum* may be administered.

If there is a tendency to chronicity, fresh Bael fruit may be given. It must, however, be both fresh and ripe, and should be prepared by being boiled, and then shredded with a fork into warm milk, pressed and strained, and then a little sugar added. A tumblerful of the milk extract of Bael fruit may be taken twice daily.

Tincture of *Mansonia ovata* in 1-drachm doses is also recommended. Other remedies resembling the above are the roots of *Pelargonium tuberosum* and *P. flabellifolium*.

With regard to individual symptoms, *collapse* should be treated by the hypodermic injection of saline, *hæmorrhage* by calcium lactate.

Very severe cases, involving the whole of the large bowel, and gangrenous cases may be treated by appendicostomy and washing out of the bowel with a weak permanganate or boric acid solution.

The simple operation is performed as follows: -The patient is placed under chloroform, after the usual antiseptic preparation of the area of the operation. An incision of about 3 inches in length is made in the usual site for the operation of appendectomy, and, the layers of the abdominal wall having been incised, the peritoneum is carefully opened, and the appendix is searched for and brought forward into the wound, so that about 1 inch protrudes. Here it is stitched by four stitches to the muscles. The wound is now closed, the appendix being fixed to the skin by a couple of stitches The wound is now dressed aseptically with a thin layer of wool and covered with collodion. The tip of the appendix is now removed and a No 8 or No. 6 catheter inserted. The wound is now dressed antiseptically and left for twenty-four hours, at the end of which time a large tube is placed in the rectum, and the whole bowel is irrigated with 1 per cent solution of bicarbonate of soda to remove the mucus, and then with a boracic acid lotion, 1 drachm to the pint. This is repeated daily, but if the case tends to become chronic a solution of silver nitrate (5 to 20 grains to the pint) is u

When the cure is effected, the small nd is easily closed.

Other methods of treatment include th lomel treatment much praised by Scheube and Kartulis, and begun lon go by the Indian physicians, and among the various forms in which it has n applied, Twining's pill of calomel, blue pill, and ipecacuanha used to be y celebrated. Plehn recommends that, after a preliminary dose of castor oil, ½ grain of lomel be administered hourly until twelve doses have been ta en during the day The treatment is discontinued during the night, and repeated in the same manner during the second and third days, after which b smuth sul trate is given in 6-grain doses hourly during the day for a long period of time.

Yellow santonin, 0·3 gramme in 8 gr mmes of olive oil, administered three times a day, has been recommended by Drake. Musgrave recommends that acetozone (strength 1 in 5,000; aerated if necessary) should be freely drunk, so as to prevent fermentation in the stomach and bowels. In all cases a mouth-wash—*e g.*, glyco-thymoline - should be ordered. During convalescence the great point is to prevent chills and indiscretions in diet, which may induce attacks of diarrhœa. Turpentine diotal and styracol, especially in combination with castor oil, have been recommended by some.

Cyllin and other similar disinfectants have been advised, but hav not given any very good results in our experience. Bolus alba has been ad ocated

Various colloidal silver preparations have been recommended

The sour-milk treatment may be tried in subacute or chronic ses, with sauerin, lacto-bacillin, fermenlactyn, or any other preparation on the market, or by using the ferment as prepared by the natives of the country. Constipation is counteracted by small doses of castor oil, liquid paraffin, Carlsbad salts, Hunyádi János, Apenta water, or enemata, but if of a marked nature should arouse suspicions of stenosis, especially if the ordinary laxative remedies do not ameliorate the condition. Under these circumstances sigmoidoscopy should be performed, and the stricture dilated by bougies or catheters.

Treatment of Dysenteric Infantile Diarrhœa.—The treatment of infantile diarrhœa and of dysentery in children is best conducted by administering a small dose of castor oil (ʒi. to ʒii.), followed by calomel (gr. ⅙) or grey powder (gr. ¼), every hour until six doses are given in a child of two years of age. The dosage may be decreased or increased according to age. Afterwards astringents such as tannigen (gr. iii.) or tannalbin (gr. v.) may be given every two to four hours.

In severe cases, due to the Shiga-Kruse or the Flexner bacillus, serum treatment is the best, 5 to 10 c.c. being injected twice daily. The diet should be altered from milk to albumen water, whey, diluted meat-juice, or clear soup.

Pain must be combated by hot fomentations, and convulsions by bromides given in gr. xv. as enemata, or in small doses by the mouth in albumen water. Chloroform may require to be administered, while some authors recommend minute doses of morphia.

Treatment of Chronic Dysentery.—The treatment of chronic dysentery varies, for sometimes the malady is easily amenable to the treatment laid down for mild cases of acute dysentery, while at other times many remedies may be tried without success. After an initial dose of castor oil, tannigen, in 3 to 8 grain, or tannalbin in 10 to 20 grain doses, in cachets, may be tried three to six times a day. In old-standing cases pilula plumbi cum opio should be given twice a day. Serum treatment should also be tried during the exacerbations, as indicated above. Bael fruit, the rind of the mangosteen, simaruba bark, etc., are all useful in this condition, and the lavage treatment is more useful than in acute cases. Rectal irrigations should always begin with 2 pints of 1 per cent. solution of bicarbonate of soda to remove the adherent mucus, and then the medicated enema may be administered, and may consist of boracic acid (1 per cent.), followed by an enema containing bismuth subnitrate and sodium salicylate suspended in a pint or less of mucilage, silver nitrate (½ to 1 grain to the ounce), copper sulphate (2 grains, with 5 minims of tincture of opium to the ounce of water), tannin (0·2 to 0·5 per cent.), resorcin (1 to 2 per cent.), creolin (1 drachm to the pint), lysol (1 per cent.), or formalin (1 in 5,000), may all be used. Silver nitrate, however, gives the best results, gr. x. to the pint. Albargin (1 in 500, 1 in 1,000) has also been recommended. Perchloride of mercury (1 in 20,000) should not be used as a rectal enema, as it is dangerous, and may increase the symptoms instead of diminishing them. In chronic or subacute obstinate cases the *vaccine treatment* first introduced for dysentery by Castellani and Greig may be tried, using vaccines prepared from the dysenteric bacilli isolated from the stools of the patient. Forster has tried this treatment also in acute cases. In our experience it gives good results in several cases of the chronic type; but in acute dysentery is much inferior to the serum and saline treatment. If all these methods of treatment fail, appendicostomy should be tried.

Diet.—There is no point in the treatment of dysentery of greater importance than the diet. The bowel requires physiological rest, and therefore, in very severe cases, the diet must be restricted to albumen water and whey, and brandy given only if absolutely necessary.

In milder cases the diet should consist of milk, which must be diluted with Perrier, soda, Vichy, or barley water, or may be mixed with powders of sodium bicarbonate (gr. vi.), potassium bicarbonate (gr. vi.), sodium chloride (gr. iii.), or sodium citrate (gr. xl.), to the pint of milk, and less in proportion. Arrowroot made with water or milk, at first thin and later thick and flavoured with a little brandy, is most useful. Benger's food and Horlick's malted milk are also useful. Strong meat-essences and alcohol should be avoided.

In all severe cases the food must be given in small quantities every two hours, about 4 ounces at a time, and must be taken very slowly, and should be neither very warm nor cold. In chronic dysentery this milk diet is of the greatest importance, and may, as already stated, be supplemented by the sour-milk treatment.

When convalescence begins, chicken-broth and milk-puddings may be added to the diet, and then lightly-boiled eggs and toast; then chicken, cream, and fish; but for a long time only white flesh should be allowed, and not much of this, for the diet should for several weeks consist largely of milk foods. Of especial importance in convalescence is the chewing of the food, and care must be taken not merely that the teeth are in good order, but that the patient is directed not to swallow any tough or very fibrous piece of food. Fruit must be avoided for a long time.

Prophylaxis.—One of the important prophylactic measures which is at present but little used, owing to practical difficulties, is the isolation of the convalescent until three bacteriological examinations of the fæces give a negative result. Another is the search for dysentery carriers in a locality in which the disease is endemic or occasionally epidemic. The treatment of a carrier must be the same as for a case of chronic dysentery, but here vaccination will be distinctly useful. The persons to be suspected are those with a history of dysentery, or with a history of having nursed a case of dysentery, and people occupied in the cooking or handling of food materials.

Another very important measure is the destruction by burning or the disinfection of the dysenteric motion by either crude carbolic acid or by Jeyes' fluid, together with its careful protection against flies before its final disposal.

The personal prophylaxis consists in drinking only filtered and boiled water, and using the same for cleaning the teeth, in avoiding salads and fresh vegetables and unripe fruit, and in carefully washing the exterior of any fruit.

With regard to public prophylaxis, a modern method of collecting and disposing of the sewage of towns is necessary everywhere in order to prevent the disease from spreading, and there is no doubt that for this purpose the best method for tropical towns is the Shone or pneumatic system, as introduced into Rangoon, Bombay, and Karachi.

Good scavenging and strict hygienic laws are necessary to prevent the breeding of flies, and if an epidemic of dysentery occurs, a special crusade against the common house-fly, if not begun before, should at once be undertaken, as has been done for other reasons in Liverpool and elsewhere, especially in America.

Dust should be diminished in the warm dry weather by the efficient watering and brushing of the roads of towns, and in this water some cheap disinfectant such as permanganate of potash should be used, especially for the more important streets.

The drinking-water of all large towns should be filtered, though it must be admitted that this alone is not a sufficient safeguard against a water-borne epidemic.

Vaccination.—Owing to bacterial dysentery being due to several different bacilli, and owing to the fact that the Shiga-Kruse bacillus is very toxic the preparation of an efficient vaccine giving a not too severe reaction is difficult.

Broth Cultures Vaccine.—Antidysentery vaccines prepared with broth cultures should never be used, as they give rise to an extremely severe local reaction, with at times abscess formation.

Peptone Water Vaccine.—Castellani, in 1904, prepared a mixed peptone water vaccine which gave fairly satisfactory results. The preparation was as follows:—The Shiga-Kruse bacillus and three other species of dysentery bacilli were grown in peptone water tubes for three days at 35° C. They were kept for an hour at the temperature of 55°-60° C., and then mixed, three parts Shiga-Kruse and one part of each of the others. Of the resulting mixed vaccine 1 c.c. (sometimes ½ c.c.) was injected, the inoculation being repeated after a week or two. The reaction was not severe. Later Castellani prepared the same vaccine without heating, adding simply ½ per cent. carbolic. According to Castellani, the very much less marked reaction noted than when using broth vaccines, is not merely due to the fact that peptone water cultures contain fewer bacilli than broth cultures.

Carbolized Emulsion Mixed Vaccine.—Since 1912 Castellani has used in Ceylon a carbolized mixed vaccine containing *B. dysenteriæ* Shiga-Kruse, Hiss-Russell Y, original Flexner, Ceylon Flexner-like No. 1, Ceylon Flexner-like No. 2. The preparation of this mixed vaccine is as follows: The individual vaccines are prepared by making emulsions from twenty-four hours' old agar cultures in normal salt solution (0·75 per cent.), to which 0·5 per cent. of carbolic acid has been added, and the individual vaccines are standardized in such a way as to contain per c.c. 1,000 million germs. These monovaccines so standardized are mixed in equal parts, so that 1 c.c. of the mixed vaccine will contain 125 millions of each of the organisms used. Of this mixed vaccine 0·5 to 0·6 c.c. is given hypodermically the first time, and the same or double the amount after a week. Agglutinins generally develop for all the inoculated germs, but their amount is not high, and may be inconstant and irregular, but the same may be said of simple monovaccines, Shiga, Flexner, etc.

It is essential to prepare the vaccine with strains which, though rich in antigen, are only slightly virulent. It is extremely rare to come across such a strain of Shiga-Kruse. A large series of strains of this species are inoculated into rabbits, and the least virulent, provided it is rich in antigen, is kept permanently as a stock culture to prepare the vaccine.

Combined Carbolized Dysentery and Typhoid and Para A and Para B Vaccine.—This vaccine has been prepared by Castellani, in 1913, following this technique:—The individual vaccines are prepared by making emulsions from twenty-four hours' old agar cultures in normal salt solution (0·75 per cent.), to which ½ per cent. carbolic has been added. The monovaccines are then standardized as follows:—Typhoid vaccine 4,000 millions per c.c., para A 1,000, para B 1,000, Shiga 1,000, Flexner 1,000, Hiss-Russell Y 1,000, Flexner Ceylon (No. 1) 1,000, Flexner Ceylon (No. 2) 1,000. The monovaccines are mixed in equal parts. The mixed vaccine will therefore contain 200 millions typhoid and 125 millions each of the other organisms used. Of this vaccine 0·5 to 0·6 c.c. is given hypodermically the first time, and the same or double the amount after a week. The reaction is somewhat more severe than after inoculation with the triple typhoid para A and para B vaccine.

In the preparation of the vaccine it is necessary to use a selected strain of Shiga-Kruse, as little virulent as possible.

Sensitized Vaccine.—An emulsion in normal saline is made from twenty-four hours' old agar cultures. To the suspension is added some undiluted dysentery serum, and after twenty-four hours it is centrifuged and the serum and saline pipetted off. The sediment is washed in normal saline, and then a suspension is made in fresh saline containing 1 per cent. carbolic, and standardized to contain 100 million bacilli or more, ½ c.c. is injected the first time, and the same or double the dose a week later.

A sensitized dysentery vaccine was first prepared and used by Broughton Alcock in 1914. It has been used later by other observers, and experiments on it have been carried out recently by Gibson. The reaction is much less severe than using broth vaccines.

Serum-Vaccine. In Japan a vaccine has been given mixed with anti-dysenteric serum, with the object of neutralizing the bacillary endotoxin with the anti-endotoxin present in the serum. The injection of such serum-vaccine does not give rise to any production of agglutinins, and the doubt has arisen, to which Gibson has called attention, that the antiserum might neutralize all the antigenic properties of the vaccine, besides neutralizing the toxin.

Gibson's 'Absorbed-Serum Vaccine.' Gibson mixes the dysentery vaccine with antidysentery serum from which the agglutinins and other antibacterial substances have been removed by means of Castellani's absorption method. Suspensions in normal saline are made from agar cultures of Shiga-Kruse, Flexner, and Y; they are standardized, and then mixed in such proportion that 1 c.c. of the mixture will contain 2,000 millions Shiga-Kruse, 2,000 millions Flexner, 2,000 millions Y.

Trivalent antidysentery serum (Shiga-Flexner-Y) is absorbed with Flexner, then with Y, then with Shiga. It is centrifuged and filtered through a Chamberland. The filtered serum is then so diluted that 1 c.c. of the resulting dilution will contain 0·4 of serum. The diluted serum and the vaccine are filled into twin non-communicating phials, which are joined together. The inoculation is carried out as follows: 0·25 c.c. is aspirated in the syringe from each phial and injected subcutaneously in the usual way. The first dose contains Shiga 500 millions, Flexner 500 millions, Hiss and Russell 500 millions, and 0·10 absorbed serum. A week later double the amount is given. This absorbed serum-vaccine gives only a very moderate reaction, and seems to induce in the blood of the inoculated persons a satisfactory amount of antibacterial substances as well as antitoxin.

Dysbackta.—This is a vaccine prepared according to a special method by Boehncke.

Lipovaccine.—A vaccine consisting of an oil emulsion of dysentery bacilli has been prepared according to Le Moignic's method. The reaction is said to be mild.

C. PSEUDO-DYSENTERIES.

Definition.—Pseudo-dysenteries are diseases other than those defined above, which give rise to diarrhœa, with the passage of blood and mucus in the motions, and are sometimes associated with abdominal pain and tenesmus, and may readily, on superficial examination, be mistaken for true dysentery.

Remarks.—It should, however, be noted that the term 'pseudo-dysentery' has been used by Kruse to signify a form of bacterial dysentery commonly found among inmates of lunatic asylums, and later to denote every variety of the disease not caused by the Shiga-Kruse bacillus.

Ætiology.—The most common causes of the pseudo-dysenteries are cancer of the intestine, especially of the rectum, inflamed piles, gummata in the rectum, cancers of the large bowel other than the rectum, and intussusception. The native habit of eating the small bones of fish along with the flesh is apt to cause irritation of the rectum and a pseudo-dysenteric attack. Inflammations of the broad ligament, especially on the left side, are apt to be confused with a mild attack of dysentery. Poisons, such as mercury, ptomaines, ricin, abrin, etc., may also produce symptoms resembling dysenteric attacks. Prout has described a form of dysentery in the Gambia due to drinking-water containing the excreta of locusts.

Diagnosis.—The diagnosis of these various conditions has already been discussed in the Diagnosis of Bacillary Dysentery, and need not be repeated.

Treatment. - The treatment must be adapted to the specific complaint, while the bowel symptoms may be relieved as indicated under the treatment of Bacillary Dysentery.

CHAPTER LXXIX

INTESTINAL SCHISTOSOMIASIS

Synonyms — Definition — History — Climatology — Ætiology — Pathology —Symptomatology —Diagnosis —Prognosis — Treatment — Prophylaxis— References.

Synonyms.—Intestinal bilharzi[illegible] Rectal bilharziosis, Hepatic bilharziosis American bilharziosis, Manson's [illegible]harziosis, Manson's disease.

Definition.—Intestinal bilharziosis is infection with *Schistosoma mansoni* Sambon, 1907, the eggs of which invade and irritate the intestines and the liver, and cause inflammation.

History.—It has long been known that the eggs found in cases of intestinal, rectal, and hepatic bilharziosis are laterally spined, as Bilharz pointed out in 1851; and Sonsino once stated that the two worms must belong to different species, but this statement did not attract attention. In 1903 Manson first suggested, on grounds of dissimilar geographical distribution, that these eggs might belong to a new species of *Schistosoma*, and in 1907 Sambon showed that a separate species really did exist, calling this *S. mansoni*, in which he has been supported by Holcomb, Firket, Broden, Grun, and others, though opposed by the great authority, Looss.

A description of the adult worms has been given by Da Silva and by Flu, confirming the differentiation of the two species.

The fact of the existence of a separate disease caused by the lateral-spined eggs of *S. mansoni* is supported by all authors who have studied the disease in America, where the patients are said never to have eggs in the urine, and never to suffer from urinary schistosomiasis. It is further supported by the work of Mathis and Baujeau on a case from Gaudeloupe, and by that of Turner in South Africa. Flu, after examining 1,000 eggs from fifteen cases of intestinal schistosomiasis in Paramaribo, never found one with a terminal spine. Reference may also be made to Letulle's paper on 'Bilharziose Intestinale,' published in 1905, to Madden's work in 1907, and to Symmer's work in 1902 and 1906, from the latter of which we have taken our two illustrations. Reference must also be made to the admirable exposition of the disease by Mathis, Noc, and Léger in 1913. In 1914 and 1915 Leiper thoroughly established the species *S. mansoni*, and worked out its life-history. He has traced the life-cycle of the parasite through the snails to its adult condition in rabbits, guinea-pigs, and man. Lutz has published his extended researches into the disease and its parasite as seen in Bahia and Northern Brazil. It will thus be seen that the recognition of the disease is becoming generally accepted, although this was by no means the case when this chapter was first written.

Climatology.—As far as is known at present, the disease exists in Egypt, Central Africa, Uganda, South Africa, the Belgian Congo, Central, South, and North America, and the West Indies. In Brazil it is confined to the northern districts, being unknown in the South. In Venezuela it is common around Caracas, where its intermediate host is believed to be *Planorbis guadelupensis* Sowerby by Iturbe and González.

Ætiology.—The cause of the disease is *Schistosoma mansoni*. The description and life-history of the parasite is given in Chapter XXIV., p. 587.

(Photomicrograph.)

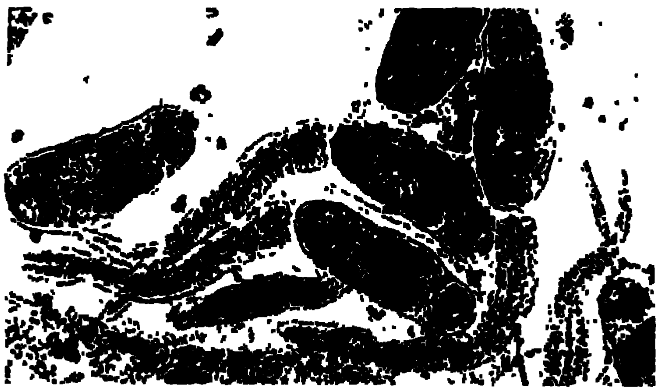

Fig. 768B.—Cercaria of *Schistosoma mansoni* from *Planorbis boissyi*.

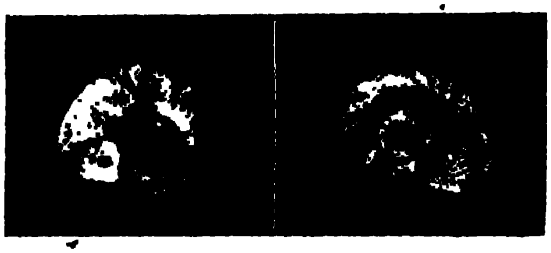

Fig. 768C.—*Planorbis boissyi*.

Pathology.—The worms live in the portal vein, but are especially attracted to the bowels, in the capillaries of which they lay their eggs, which burst those vessels, and escape into the mucosa, causing therein a dense cellular infiltration, which leads to a thickening of the coats of the bowel, and to the formation of papillomata, which may become detached and form ulcers. Dense fibrous infiltration of the peritoneum may also occur, and contain both eggs and worms. The mucosa of the bowel is protected by a quantity of mucus. In the rectum the mucus membrane is apt to become hypertrophied, and to grow, forming large polypoid masses, or adenomata, which may protrude through the anus. The ova may affect the subcutaneous tissue of the sacral and coccygeal regions,

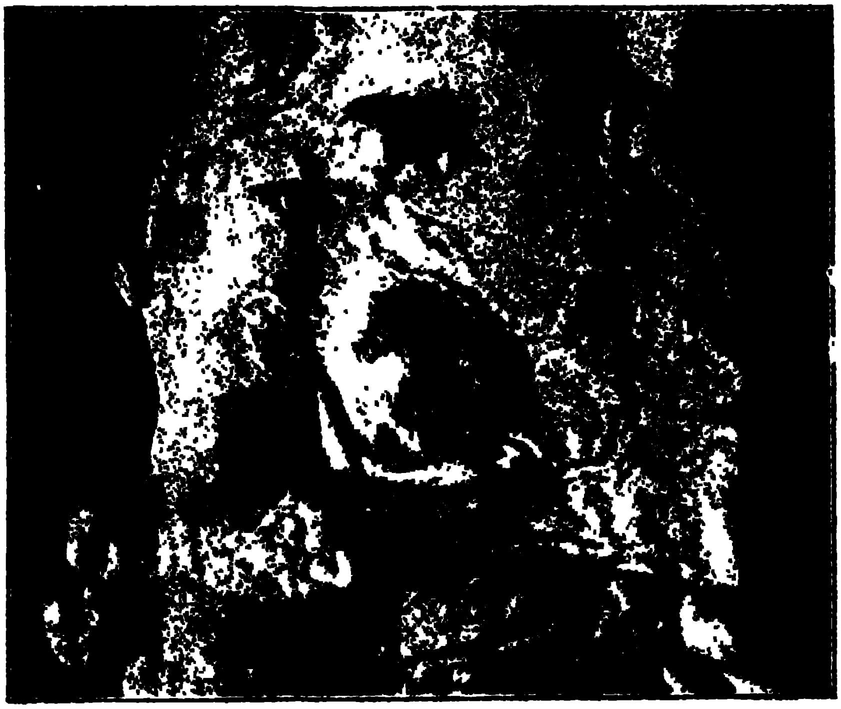

FIG. 769.—INTESTINAL SCHISTOSOMIASIS.
(After Symmers.)
Polypoid growths in descending colon.

FIG. 769A.—BOWEL IN A CASE OF INTESTINAL SCHISTOSOMIASIS.

and cause dense cellular infiltrations, giving rise to fistulæ, which may spread and infect a large cutaneous area.

When the ova reach the liver by the blood-stream, they give rise to fibrous-tissue formation or an abscess. The surface of the liver shows in places a whitish network and also flat, china-white plaques. On section a marked increase in Glisson's capsule may be seen, the portal vessels lying in circular or slightly oval areas of connective tissue. Gall-stones may also form round the ova in the gall-bladder. The pancreas and spleen may also be infected, and the vulva and vagina.

The ova may also reach the lungs, causing a chronic interstitial pneumonia, and, passing through these organs, may enter the heart and the general circulation.

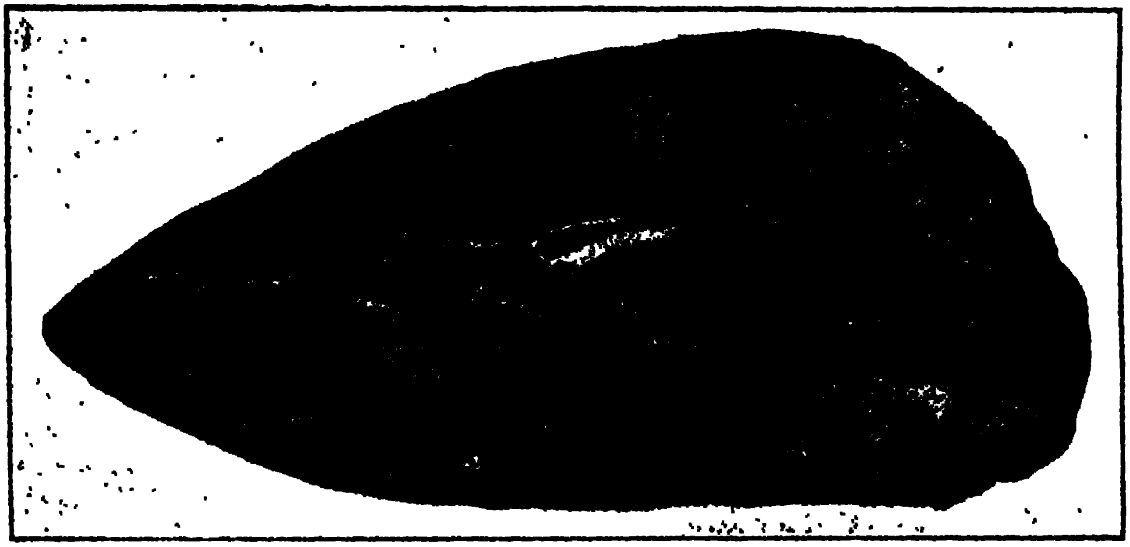

FIG. 770.—LIVER IN INTESTINAL SCHISTOSOMIASIS
(After Symmers)
Shows the increase of fibrous tissue in the portal canals.

Symptomatology.—The incubation period seems to be one to three months. The clinical appearances of the disease may be classified into four varieties:—

1. Slight infections.
2. Schistosomic dysentery.
3. Schistosomic tumours.
4. Schistosomic fever.

Slight Infections.—In these cases there are no symptoms, and the disease is discovered by the examination of the fæces by a microscope.

Schistosomic Dysentery.—The symptoms resemble those of chronic dysentery, consisting of pains in the abdomen and the passage of blood and mucus. The fæces contain the characteristic ova. The attack begins with a hypersecretion of mucus, followed by frequent small motions containing but little fæcal matter and much mucus. The result of these frequent motions is to cause prolapse of the rectum. Papillomatous growths may form in the rectum, and can be distinguished from piles by their large number. They may protrude from the anus, when the removal and microscopical examination of a small portion will clear up the diagnosis. When the lower part of the rectum is involved, much agony from tenesmus and constant desire to defæcate is experienced. The rectal prolapse becomes very distressing, as it has to be constantly replaced by the patient himself, and as both the mucous membrane of the bowel and that of the anus become much inflamed and irritated.

In cases in which there is much sclerosis, with a scarcity or absence of polypi, the dysenteric symptoms are not so marked. On the contrary, the patient complains of constipation, not relievable by ordinary methods, alternating with bouts of diarrhœa.

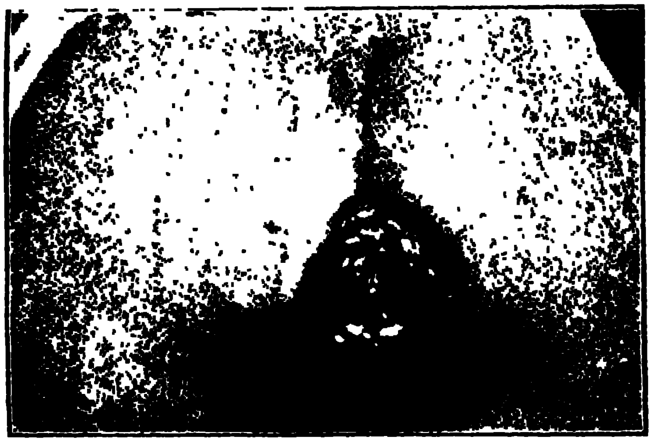

FIG. 771.—PROLAPSE OF THE RECTUM IN INTESTINAL SCHISTOSOMIASIS. (From a photograph by Christopherson.)

Schistosomic Tumours.- When an emaciated patient in one of the endemic regions is examined, one or more abdominal tumours may be found in the region of the cæcum or colon. These tumours, which are fairly hard, are somewhat movable, and are usually elongated, with the long axis corresponding to the direction of the long axis of the bowel in the region in which the tumour is lying. The tumour, accidentally discovered, continues to increase in size for months and years, while the patient becomes very emaciated, and suffers from attacks of colic at times.

Liver and Pancreas.- The liver may be found to be enlarged and cirrhotic, the spleen also be enlarged, and there may be signs of cirrhosis of the pancreas.

If the patient removes from the endemic area, improvement will take place; but if he remains, then no cure appears to be possible, and he dies sooner or later from exhaustion.

Blood.—The blood in intestinal schistosomiasis requires further study, but it would appear that usually there is a marked anæmia, with oligochromæmia, slight leucocytosis, and very slight eosinophilia.

Urine.—In cases uncomplicated with the presence of *S. hæmatobium* there is no albumen, no sugar, and no ova in the urine.

Schistosomic Fever.—Flu in 1911 reported that *Schistosoma mansoni* could give rise to an illness resembling katayama disease. Archibald has also called attention to the fact that intestinal schistosomiasis caused by *S. mansoni* is capable of producing a fever associated with splenomegaly, enlargement of liver, a polymorphonuclear leucocytosis and lymphocytosis, together with a diminution or absence of eosinophiles. The absence of eosinophilia was constantly noted in intestinal schistosomiasis in contrast to urinary schistosomiasis when the reverse holds good. Two cases treated with an autogenous vaccine of the predominant coli organisms present in the stools derived benefit and lessened the symptoms of intestinal toxæmia.

Urticaria has been noted by Lawton, who reports also presence of eosinophilia.

Complications.—A case may be complicated with urinary bilharziosis, ankylostomiasis, and other intestinal parasitic diseases.

Diagnosis.—The diagnosis must be made by finding the characteristic lateral-spined eggs in the fæces.

Prognosis.—The prognosis is unfavourable. It must be noted, however, that in some cases the parasite does not give rise to any distinct pathological symptoms for a long time. One of us has observed in Uganda several natives with eggs of *S. mansoni* in their fæces, although they were apparently in good health. The stools, apart from the eggs of the worm, were normal.

Treatment. Christopherson has recommended the intravenous injection of tartar emetic (antimonium tartaratum). He gives ½ grain dissolved in 2[illegible] of distilled water, and diluted with two volumes of normal saline at the time of use. The dose is increased by ½ grain every other day until 2 grains are reached, and this dose is continued until 30 grains in all have been injected. In children he began with ¼ grain for a boy of ten years. Care has to be taken to avoid acute or chronic antimony poisoning, and the maximum dose for a boy of ten is given as 1 grain, for an adult 2 to 3 grains. The drug appears to have a cumulative action.

Christopherson's results have been confirmed by Low, Taylor and others.

Filix mas may be administered with the purpose of eradicating the worms, and symptomatic treatment may be carried out as mentioned under Urinary Bilharziosis. Madden advises an enterotomy and a cleaning out of the bowel, when a tumour can be felt, and a Whitehead's operation may be done to relieve the rectal symptoms. Vincent has suggested that large intestinal irrigations of a solution of sodium hypochlorite (8 to 10 per 1,000) should be given, and other authorities tannic acid enemata (3 per 1,000). Some authorities recommend the intravenous or intramuscular injections of salvarsan, and others the use of emetine.

Prophylaxis.—This is based principally on Leiper's work. Filtered water should be used for all personal purposes. If this is not possible, tap-water should be stored for forty-eight hours before use, as freshly discharged cercariæ do not usually live in it for more than twenty-four hours. Chemical sterilization may be carried out by using sodium bisulphate tablets, each containing 1 grm. of the chemical. Two tablets are dissolved in a quart water bottle. Leiper has shown that sodium bisulphate in a dilution of 1 in 1,000 is lethal to the cercariæ. For small detachments of troops in outside districts Leiper recommends that the drinking-water should be separated from ablution water, the former being sterilized by boiling or by tablets of acid sulphate of soda, while the ablution water should be rendered safe for immediate use by adding ordinary Cresol in the dilution 1 in 10,000.

CHAPTER LXXX

EPIDEMIC GANGRENOUS RECTITIS

Synonyms.—Caribi (British Guiana), El bicho (Venezuela).

Definition.—An endemic very contagious disease of South America, and perhaps Fiji and other South Pacific Islands, of unknown causation, and characterized by dysenteric symptoms leading to prolapse and gangrene of the rectum, or at times to disease of the colon.

History.—Chalmers and Archibald, in 1914, drew attention to the fact that an eighteenth-century writer, D. L. F., in his work entitled 'Traité des maladies particulières aux pays orientaux,' had described this disease in Brazil under the name of 'bicho.' His report is similar to the latest information on the subject, which is curious. He wrote as follows:—

> ‘DU MAL QUE LES PORTUGAIS APPELLENT BICHO.’
>
> ‘Les Portugais habituez au Brésil appellent encore Bicho, une inflammation du fondement, qui est également fréquente et dangereuse dans ce pays, elle est toujours suivie du mal de tête, d'épreintes, grande chaleur en la partie malade, et quelquefois de la fièvre. Si l'on la néglige il s'y fait en peu de jours des ulceres venimeux, qui ont donné lieu au nom de Bicho.
>
> ‘Ceux qui se lavent souvent ces parties, sont moins sujets à cette incommodité que ceux qui ne le font pas. D'abord qu'on s'en croit attaqué, il faut étuver plusieurs fois le jour, la partie avec une décoction de limons, à laquelle on ajoutera quelques grains de sel. L'on introduit aussi heureusement dans l'intestin, des petits quartiers de limon, et cela arrete quelques-fois le mal tout court dans son commencement; s'il y a déja une corruption notable, l'on à de coutume de détremper de la poudre à canon dans de l'eau de rose, ou de l'eau de plantain, et de ce liniment l'on en imbibe de petits linges, que l'on met dans le fondement. Après l'avoir bien étuvé avec la décoction de limons, quoy qu'il y ait de la fièvre, il faut bien se donner garde de saigner dans cette occasion, l'expérience ayant fait connoître que ce remède est fort préjudiciable: l'on peut seulement donner fréquemment les lavement anodins ou détersifs, suivant que la corruption ou l'inflammation, sont plus ou moins grandes, et purger doucement sur la fin.’

More than one hundred and fifty years later Ackers of Curaçoa gave Manson an account of the disease as seen in Venezuela. It appears to us that some endeavour should be made to discover the ætiology of this disease and to study it by modern methods, which ought to be easy in an endemic area where animals are attacked.

Climatology.—The disease is apparently known in Brazil, British Guiana, and Venezuela, and with perhaps the addition of Fiji and other islands in the South Pacific.

Ætiology.—This is entirely unknown. The disease occurs in man and animals, fowls, dogs and calves, and is said to be very contagious. The Venezuelan natives say that it arises from children chewing the green tender stalks of unripe maize.

Pathology.—The disease presents two pathological pictures—viz., *a high infection* in the colon, which is rare, and *a low infection* in the rectum.

Symptomatology.—The disease begins as an itching about the anus, followed by symptoms of acute dysentery, which increase in severity until there is a constant discharge of blood-stained or greenish fœtid fluid. Prolapse and gangrene of the rectum may now occur, or convulsions may supervene, but in either case the patient dies.

Diagnosis.—In an endemic area severe dysenteric symptoms in a native child would lead one to suspect the disease.

Prognosis.—This is extremely bad, as the disease appears to be always fatal.

Treatment.—Natives treat the disease by enemata of strong lemon-juice mixed with dilute rum, a dose of castor oil being given at the same time. Enemata and decoctions of *Spigelia anthelmia* are also prescribed. In children a portion of a lemon is roasted and inserted *per anum*. According to local medical men, this native treatment is more efficacious than boric acid and similar enemata.

Prophylaxis.—Nothing can be said with regard to this until the disease is scientifically investigated and its ætiology discovered.

CHAPTER LXXXI

DISEASES OF THE RESPIRATORY ORGANS

General remarks—Rhinitis spastica vasomotoria—Gangosa—Hirudiniasis—Rhinal chilopodiasis—Linguatuliasis—Rhino-pharyngitis spirochætica—Bronchial spirochætosis—Tropical bronchomycoses—Pulmonary nocardiasis—References.

GENERAL REMARKS.

DISEASES of the respiratory organs are of common occurrence in the tropics, in the form of acute or chronic inflammation of the nose, throat, larynx, bronchi, or lungs. *Pneumonia* is less common than in Europe, and must be carefully diagnosed from pneumonic plague, liver abscess, and malaria, by careful physical examination, as well as by microscopical examination of the sputum and blood. Liver abscess may burst into the lung or pleural cavity, and may cause the expectoration of a peculiarly brown and viscid sputum. *Emphysema* and *asthma* are fairly common, and all types of bronchitis are met with, though more rarely than in temperate zones.

Phthisis is common, and appears to be increasing in the East, but it must be remembered that the pulmonary lesions of paragonimiasis, histoplasmosis, bronchospirochætosis, and certain bronchomycoses, closely simulate this disease, and the examination of the sputum is imperative. The occurrence of Porocephalus in the lungs must also be remembered, and the intense congestion in heat-stroke. There are several conditions which deserve special mention with regard to tropical disease.

RHINITIS SPASTICA VASOMOTORIA.

Synonyms.—Rhinitis nervosa, Coryza spasmodica, Dispnée tropicale, Tropical hay fever.

Definition.—A rhinitis characterized by fits of sneezing, with the production of much nasal mucus, and obstruction of the nose from swelling of the mucous membrane over the turbinated bones. The affection has the greatest resemblance to hay fever.

History.—This disease appears to have been first described by Zegers in 1901, in Batavia, while Brero gives a full description in Mense's 'Tropenkrankheiten,' and we have seen several cases in Ceylon. O'Zoux has recorded numerous cases in the island of Réunion.

Symptomatology.—The affection is characterized by attacking adults, in whom it causes violent fits of sneezing, lasting from a few minutes to two hours, during which time the victim sneezes ten to seventy times, while fluid pours from the nose, tears roll down from the eyes, the conjunctivæ are injected, the eyelids swollen, the head aches, and the patient is unable to do his work. The attacks are repeated constantly, and may take place several times during the day, or may not recur for weeks. They may be associated with or followed by dyspnœic conditions resembling to some extent asthma. At the beginning the mucosa of the inferior turbinated bone may appear hyperæmic, but later it becomes swollen, and has a macerated appearance. The disease therefore closely resembles hay fever, but is supposed to be caused by dust acting upon the nasal mucosa of persons, the resistance of whose nervous system has been lowered by long residence in the tropics. We have frequently met with the disease in people exposed to the dust of tea and copra.

Treatment.—The only successful treatment in many cases is a change of climate, when the symptoms stop at once. When the patient cannot have a change of climate, atropine and strychnine pills, or small doses of quinine, may be recommended, and locally a spray of a solution of cocaine (½ or 1 per cent.) and adrenalin (1–2 per cent.).

GANGOSA.

Synonyms.—Rhinopharyngitis mutilans (Leys); Granuloma gangrenosum; Kaninloma (Fiji).

Definition.—Gangosa is an ulcerative condition of the palate, nose, pharynx, and skin surfaces of the body, of unknown cause, though possibly a late sequela of yaws, which slowly spreads to the nose and larynx, destroying cartilage and bone, and causing much deformity.

History.—The disease appears to have been first described in 1828 by a Spanish Royal Commission to the Marianne or Ladrone Islands under the name 'gangosa,' which means 'nasal voice,' and is derived from *gangoser*, 'to snuffle.' It was carefully studied by Seligmann in British New Guinea in 1898 and 1904, who describes the implication of the skin of the face, and draws attention to the fact that it is the disease described by Sir William MacGregor as lupus and by the white residents as cancer. In 1906 the disease in the endemic area was studied by Fordyce and Arnold, by Leys in Guam, an island to the south of the Ladrone Islands, and by Mink and McLean in the Ladrone and Caroline Islands. In 1907 a paper appeared by Musgrave and Marshall on a case from the Batanes Islands, 120 miles north of Luzon, and by Stitt on a case in a European in Guam. It has been studied by Angeny and Kerr. Breinl has found it on Murray Island, and thinks that it closely resembles the condition known in Fiji as Kaninloma.

Climatology.—There appears to be an endemic area for the disease, it being common in the Batanes Islands (where the cases are mistaken for leprosy), in the Ladrone Islands, Guam, and the Caroline Islands. Cases occur also in Fiji, Murray Island, Panama, British Guiana, Ceylon, Nevis, Dominica, and Equatorial Africa. In the Anglo-Egyptian Sudan there is a disease closely resembling gangosa, though probably syphilitic.

Ætiology.—Daniels and several other authors believe it to be a sequel to yaws, but Rat is opposed to this, as are Mink, McLean, Musgrave, and Marshall and Angeny, who point out that the disease is absent or very rare in many countries where yaws is common. Kerr, however, has noted that yaws is an almost constant antecedent of gangosa. Alverez suggested that it was syphilis, but Musgrave, Marshall, and Leys are opposed to this, because no syphilis exists in Guam, where gangosa is common. There are no signs or symptoms of syphilis in this disease. Treponemata cannot be found, and mercury is without effect. It is not leprosy, because of the absence of nodules, infiltration, anaesthesia, and Hansen's bacillus. It is distinguished from epithelioma by the absence of the histological characters and metastases, as well as by the rapid onset and protracted course. It is excluded from tuberculosis by the absence of Koch's bacillus and other symptoms of the disease, and the failure to inoculate guinea-pigs successfully. It may therefore be a separate disease of unknown causation, though we believe that it is probably a late manifestation of yaws. Schnitter regards it as a sequela of a special variety of yaws. It appears to be equally common in males and females.

Pathology.—It appears to begin sometimes as a sore throat or coryza, or as a tubercle on the palate. In any case, an ulcer soon forms, which, though superficial at first, eats through cartilage and bone, with periods of quiescence and of activity. This ulceration is due to a necrosis of the tissue elements, with very little reaction on the part of the body. This reaction is apparently limited to a small-celled infiltration, some giant-celled formation, and proliferation of bloodvessels with formation of granulation tissue.

Morbid Anatomy.—The post-mortem may reveal signs of some concomitant affection—for example, tuberculosis, pleurisy, or cardiac hypertrophy—which have nothing to do with the disease, the important features of which are ulceration and destruction, together with scar formation in the larynx, pharynx, palate, nose, and perhaps the antrum of Highmore.

Histopathology.—Microscopically, the following changes are observed as the diseased area is approached from healthy tissue: First there is an œdematous infiltration, then an infiltration with round cells, which are principally lymphocytes, associated with another variety possessing more protoplasm, and a small dark nucleus. Sometimes there are giant cells and proliferating vessels, and there are always hæmorrhages. Then comes a layer of necrosis, forming the surface of the ulcer, at the edges of which the epithelium can be seen sending processes into the subcutaneous tissue, which consist of large vacuolated cells with pale vesicular nuclei. Some diplococci, micrococci, and bacilli have been noted, but no acid-fast bacilli or Treponemata have been seen.

Symptomatology.—The disease begins sometimes as a sore throat, and on examination a nodule may be seen on the back of the pharynx, the posterior pillars of the fauces, or the edge of the soft palate. This becomes a superficial ulcer covered with a brownish-grey slough. This ulcer spreads rapidly at first, but more slowly later, and eats away first the soft parts, and then the bone of the palate, the nasal septum, and the cartilages of the nose, so that the skin falls in, and the nose and mouth are converted into one cavity. It may then extend on to the face or lip, or affect the larynx. When it spreads over the face it may involve the eyelids, erode the cornea, and even destroy the vision. In some advanced cases the entire front of the face is replaced by a large opening ringed about by foul ulcers. Sensation is diminished over the ulcer, and a most objectionable odour is exhaled, while a slight discharge of granular and necrotic débris is generally present. The ulcers may also appear on the skin of the extremities or on parts of the body not usually covered

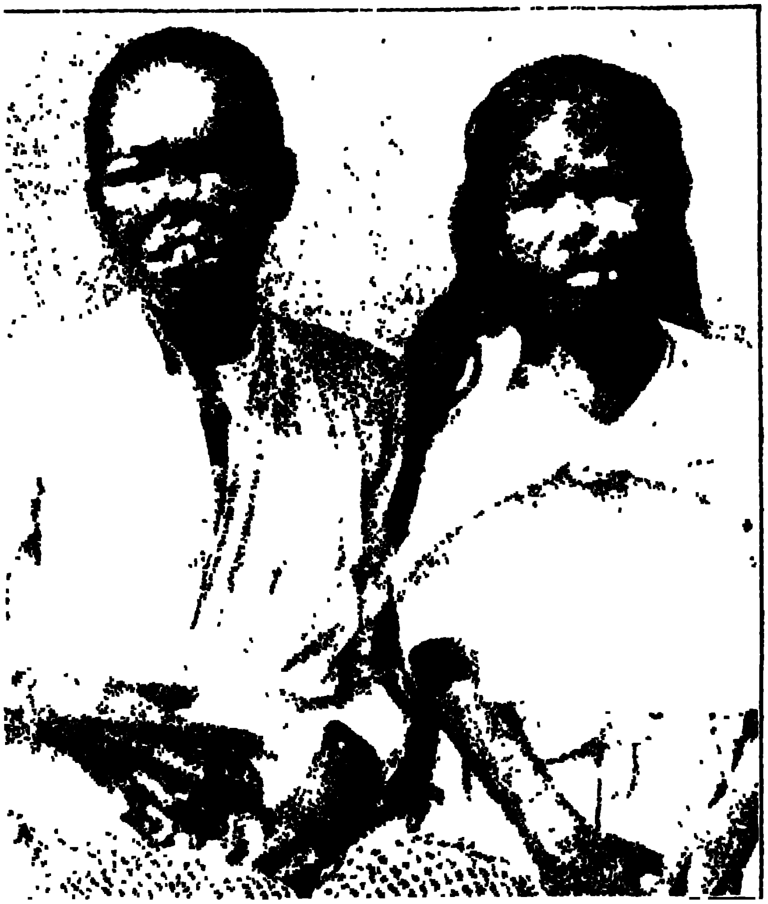

FIG. 772.—GANGOSA.
(From a photograph by Arnold.)

with the clothing. At times the ulcers may remain quite superficial, spreading at one edge while healing at another. Scarring similar to that seen after burns may result, which by contraction may lead to obliteration of the palpebral fissures, the nasal orifices, and to reduce the size of the mouth, as well as to produce great deformities in the hands and feet. It may cause a chronic osteitis resembling that seen in syphilis. It appears to be in some way self-limited, as it does not attack the trachea or genital organs. The ulceration may progress continuously for a period of ten to thirty-five years, or it may advance at certain times and be quiescent at others, or it may cease at any time, leaving a chronic ulcer. Its duration varies, therefore, from a few months to many years.

With regard to the blood, Musgrave and Marshall report that their case showed no marked leucocytosis and no abnormal elements. The hæmoglobin was 80 per cent., the leucocytes 11,600 per cubic millimetre, the small lymphocytes 10 per cent., large lymphocytes 4·6 per cent., polymorphonuclears 82 per cent., eosinophiles 2·6 per cent., basophiles 0·4 per cent. Wassermann's reaction is often positive. Kerr believes this to be due to pregressed yaws. Noguchi's cuti-reaction may be positive.

The disease is not limited to the throat and nose, but, as already stated, may spread to the face or appear on the extremities, but as a rule the general health is but little affected.

Variety.—A fulminating variety has been described by Mink and McLean in children, which is fatal in forty-eight hours, and closely resembles diphtheria, without, however, the presence of the specific bacilli.

Diagnosis.—The diagnosis has been practically discussed in the Ætiology, and need not be repeated, except to say that it must be made by a process of exclusion.

Prognosis.—The disease is rarely fatal, and all cases tend to ultimate recovery, but the course is very long and the disfigurement great. The general health is also good as a rule, although death may take place from intercurrent disorders, such as tuberculosis, dysentery, and other internal causes.

Treatment.—Mercury is useless and potassium iodide has little action on the condition. Salvarsan and neosalvarsan, or their substitutes, seem to give much better results. An application of a strong solution (1 per cent.) of permanganate of potash is recommended as a deodorant, and local application of tincture of iodine or the actual cautery.

Prophylaxis.—Nothing definite can be said under this heading, as the ætiology is not known with certainty, but segregation of the patients in a colony or special hospital until they are cured is advisable. In Guam, according to Angeny, the disease is steadily decreasing, thanks to the measures taken of segregating the patients, and possibly to the thorough treatment of yaws patients, and also probably to the improvement in general sanitation since the American occupation.

HIRUDINIASIS.

Definition.—Hirudiniasis is the invasion of the nose, mouth, pharynx, or larynx by leeches.

Remarks.—Leeches have already been described in Chapter XXVII. (p. 683), when it was mentioned that they were apt to invade the nose, mouth, pharynx, or larynx. Masterman has given a very excellent account of hirudiniasis as seen in Palestine.

Climatology.—Leeches are most troublesome in Algeria, Palestine, and Ceylon, less so in the Philippine Islands, Java, Sumatra, Australia, and Japan.

Ætiology.—It is the water-leech, which lives in springs, which is the cause of the trouble to man, as it is apt to be swallowed with drinking-water. This is particularly liable to take place when the traveller drinks the water hastily at dusk.

Pathology.—The leech, when in the mouth, nose, pharynx, or larynx, does not suck blood until gorged, and then detaches itself from the affected part, as is the rule when it attacks the skin, but apparently bites and sucks a little in one place, and then passes to another, and bites and sucks again, and so on. Of course the sites of the bites bleed, and hence the patient may in course of time become very anæmic, and even die. It is hardly likely that a leech could live in the stomach if swallowed, though such an occurrence has been described.

Symptomatology.—The patient usually knows that he has swallowed a leech, and has felt the animal catch hold of the mucosa of the pharynx during the swallowing of the water. But children, and even adults, may be quite unaware of the accident having happened. The most important sign is the bleeding from the nose or mouth, or the hawking up of blood from the pharynx, or hæmoptysis from the larynx, accompanied by a short irritating cough, dyspnœa, and sometimes cyanosis from the impediment to the respiration. Rhinoscopic or laryngoscopic examination may be necessary in order to see the parasite, and will require to be done with cocaine. In the larynx the head of the leech is usually fixed just inside or outside of the vocal cords, and the body may flop backwards and forwards with respiration.

Diagnosis.—The bleeding and the examination with a nasal speculum or a laryngoscope make the diagnosis easy.

Prognosis.—This is usually good if the parasite is removed in time, but if left for long, removal may be too late, and the patient succumb.

Treatment.—Apply a pledget of cotton-wool soaked in 30 per cent. solution of cocaine to the parasite. This produces a paralyzing effect on the animal, and it can then be removed. As, however, the drug requires some time to act, and the leech might fall from the larynx into the trachea, it is advisable to make the patient lie prone on a couch, with the head hanging over, when the paralyzed parasite will be coughed up.

Prophylaxis.—Filtration of the water will prevent the parasite entering the body. Masterman says that a kind of carp, *Capoëta fraterculu*, will keep the water free from leeches.

RHINAL CHILOPODIASIS.

Definition.—Rhinal chilopodiasis is the invasion of the nose by a species of the *Chilopoda* (see p. 739).

Ætiology and Symptomatology.—The *Chilopoda* have already been described in Chapter XXVIII., and it has been pointed out that *Geophilus carpophagus* Leach, *G. similis* Leach, *G. electricus* Leach, *G. cephalicus* Wood, *Lithobius forficatus* Leach, and *L. melanops* have been found in the nasal cavities, causing inflammation, with at times a great flow of mucus, while at others there is a stoppage of the discharge. Associated with this flow there is headache, with more or less marked remissions at times, and also general symptoms, such as convulsions, angina, dyspnœa, etc., which are thought to be produced reflexly by stimulation of the fifth nerve. The symptoms are thought to be produced mechanically, and not to be due to any action of venom secreted by the parasite.

Diagnosis is to be made by examination of the nose by a speculum.

Treatment.—The affection is not serious, and often the parasite is expelled by merely sneezing. More rarely chloroform-water injections, snuff, eau-de-Cologne, or turpentine injections are needed. Still more rarely will a sinus, such as the frontal sinus, require to be opened.

LINGUATULIASIS.

Linguatula serrata Frölich, 1789, has been found occasionally in the nose of man in Europe and in the tropics (*vide* p. 732).

RHINO-PHARYNGITIS SPIROCHÆTICA.

Definition.—A rhino-pharyngitis characterized by the presence of numerous spirochætes in the nasal and pharyngeal secretion.

Historical and Geographical.—This affection has been described by Castellani, who has found cases of it in the tropics, in the Balcanic-Adriatic zone, and one in England.

Ætiology.—In the nasal and pharyngeal secretion large numbers of spirochætes are present at the beginning of the attack, while other organisms are practically absent; in a later stage, however, bacteria are present in great abundance. The spirochæte found—*Spiroschaudinnia minuta* Castellani—is very delicate, more delicate than *S. bronchialis*. It can be put in evidence by the ultra-microscope, or by staining with various modifications of Romanowsky, the best for this particular spirochæte being apparently Jenner's modification. Silver methods of staining (especially using Fontana-Tribondeau's technique) give good results. In preparations stained with Romanowsky, or other modifications of this method, the organism takes often a pinkish-red or purplish tinge. The length of the organism varies from 3 to 10 or 12 or more microns. The beginner should be careful not to mistake for spirochætes undulating fibrin threads, particles of detached ciliated epithelium, and detached cilia.

Symptomatology.—The affection does not clinically differ from an ordinary attack of coryza. There is sneezing, sero-mucous nasal discharge, occasionally a slight cough. The patient may complain of headache, and there may be some slight fever.

In a few days, as a rule, all the symptoms disappear, but occasionally the affection may run a much longer course, and may spread to the larynx, trachea, and bronchi. In two cases of bronchitis following an attack of spirochætic coryza above described Castellani observed in the expectoration the same type of spirochæte, and it would appear, therefore, that there may be several types of bronchial spirochætosis.

Diagnosis.—This is based on the microscopical examination of the nasal and pharyngeal secretion. The beginner should be careful not to recognize as spirochætes detached cilia and segments of undulating fibrin threads.

Prognosis.—This appears to be favourable.

Treatment.—A carbolic cocaine spray (carbolic acid 3 minims, cocaine hydrochloride 1 grain, water 1 ounce) will be found useful. Aspirin, pyramidon, and quinine may be administered internally in 5 grain doses three or four times daily. In cases running a protracted course arsenic may be tried.

In a few cases of naso-pharyngitis preceding, at times, typical cases of bronchospirochætosis the nasal and pharyngeal secretion may contain *S. bronchialis*, though this is rare. Several ætiological types of nasal spirochætosis might therefore be, perhaps, distinguished. In the tropics one comes across occasionally ulcerative affections of the nose, with presence of numerous coarse spirochætes and *Bacillus fusiformis*, but these conditions have nothing to do with true rhino-pharyngitis spirochætica.

BRONCHIAL SPIROCHÆTOSIS.

Synonyms.—Castellani's bronchitis (Galli Valerio). Spirochétose bronchopulmonaire de Castellani (Violle). Bronchite sanglante (Violle).

Definition.—A type of bronchitis and broncho-alveolitis characterized by the presence of enormous numbers of spirochætes in the expectoration.

History.—The affection was described by Castellani in 1905 and 1906. He named the causative spirochæte *S. bronchialis* in 1907. Castellani's findings were speedily confirmed by Branch, in 1906 and 1907, in Kingstown, St. Vincent, and by Jackson, in 1908, in the Philippine Islands. In 1909 Waters described numerous cases of the disease occurring in India, and Phalen and Kilbourne a case in the Philippine Islands, where, in 1911, Chamberlain recorded two further cases.

In 1913 Chalmers and O'Farrell carried out an investigation on the malady in the Sudan, and succeeded in reproducing it in a monkey. In 1914 Taylor investigated the condition in Uganda. In 1915 Fantham published a classical paper on *Spirochæta bronchialis*, studying it completely from a morphological point of view, and described its granular stage and the intracellular forms of the parasite.

In the same year Macfie reported cases from West Africa, and

Galli Valerio recorded several interesting cases of the malady in Switzerland, and Lurie one in Serbia. In 1917 Galli Valerio recorded further cases in Switzerland. In 1917 Violle first discovered the affection in France, making a very complete investigation and publishing numerous papers on it. Violle's observations stimulated further research in France, and a number of cases of the malady were reported by Bine, Dide, and Ribereau, by Netter, by Dalimier, by Barbary, and others. Alcock has described a case in an English soldier in the North of Italy. Villa and, later, Corvetto have recorded cases in South America.

Geographical.—The disease has probably a cosmopolitan distribution. It has been found in Ceylon, India, Philippine Islands, China and Indo China, North and Equatorial Africa, being especially common in the Sudan, West Indies, America, and recently in Europe in the Balkans, Italy, Switzerland, France, and England.

Ætiology.—The disease is due to *S. bronchialis* Castellani, 1907. The parasite has been further investigated by several observers, and in a masterly manner, in 1914, by Fantham, who described its coccoid and intracellular stages. The organism is extremely polymorphic, being very variable in length, thickness, and the number of waves. One may distinguish thick and thin forms, long, short, and intermediate types. The length may vary between 5 and 30 microns, its breadth between 0·2 and 0·6 micron. A number of the parasites are between 14 and 16 microns, or 7 and 10 microns, the latter resulting, as shown by Fantham, from transverse division of the former.

The ends are of variable shape, but mostly somewhat acuminate. The number of spirals varies between two and eight. Flagella seem to be absent, but Fantham has noticed the presence of a delicate membrane or 'crista' in certain specimens.

In fresh preparations *S. bronchialis* is actively motile for only a short time; the motile phase, as demonstrated by Fantham, is succeeded by one of granule formation the granules or coccoid bodies representing a resting stage from which new spirochætes develop. Fantham has carefully compared *S. bronchialis* with the common mouth spirochætes, and has come to the conclusion that they differ in several features. *S. bronchialis* is more actively motile than the oral spirochætes; it dies, as observed first by Chalmers and O'Farrell, and later by Taylor, very quickly in fresh preparations, while the oral spirochætes may live for hours outside the human mouth. Coccoid bodies are much more frequently produced by *S. bronchialis* than by the spirochætes of the mouth. Intracellular stages are occasionally seen in the case of *S. bronchialis*, but not in the case of spirochætes from the mouth. *S. bronchialis* stains with more difficulty than the oral spirochætes, is slenderer than one of them, *S. buccalis*, and does not appear to produce pseudo-membranes.

Predisposing Causes.—A chill acts, in our experience, as a very important predisposing or secondary cause.

Experimental Reproduction.—Chalmers and O'Farrell have succeeded in reproducing the disease in monkeys. Cases of human laboratory infections have been recorded by some authorities. Attempts to infect guinea-pigs and rabbits have failed.

Method of Infection.—Infection takes place from infected to healthy persons, the spray exhaled in coughing, etc., being contaminated with the spirochætes or, more probably, according to Fantham, with the resistant coccoid bodies produced by *S. bronchialis*. It is also probable that a certain number of persons may harbour *S. bronchialis*, and that a chill or any cause decreasing their organic resistance may induce an increase in its virulence in the same way that a chill may act on the pneumococcus. To this latter possibility Violle and others have called attention.

Symptomatology.—Three types of the disease may be distinguished —the acute type, the subacute type, the chronic type.

Acute Bronchospirochætosis.—In the acute type the patient feels chilly and develops fever, which generally is not very high, rarely exceeding 103° F. The fever may last between two and eight days. The patient coughs a great deal, and may have rheumatoid pains all over the body. The expectoration is scanty, muco-purulent, very seldom containing traces of blood. In most cases the general condition of the patient is not much affected; in others the patient feels very tired and ill.

Subacute Bronchospirochætosis.—The attack begins suddenly or gradually, and lasts between two and several weeks; in many cases there is very little or no fever, and the general condition of the patient may be fairly satisfactory. The cough is frequent and there is often expectoration of pink jelly-like mucus, and true hæmoptysis may take place. The physical examination of the chest may reveal nothing at all, or only signs of simple bronchitis; but at times patches of slight dulness with crepitations may be observed. The blood may show a slight degree of anæmia, but the number of leucocytes is normal, and so is the differential leucocytic count.

Chronic Bronchospirochætosis.—Chronic bronchial spirochætosis may follow on an acute or subacute attack or several such attacks, but frequently the onset is quite insidious and slow. The patient has a chronic cough, which is in certain cases more severe in the morning. The expectoration is not very abundant, and may be muco-purulent in character, but in many cases for periods of two or three days, and even much longer, the expectoration contains blood. Sometimes attacks of genuine hæmoptysis occur, one or two teaspoonfuls or much more of blood being expectorated. In some cases there is no fever; in others a true hectic-like fever may be present. In some cases, however, the rise of temperature takes place in the morning, and not in the afternoon; in others the fever is present only occasionally, and is very irregular. The physical examination of the chest reveals in many cases very little except a few dry or coarse moist râles. In others there may be signs of consolidation. The general condition may remain fairly good for a long time, though a certain degree of anæmia is often present. A few cases waste rapidly.

The course of the disease may be prolonged, with periods of great improvement and even apparent cure.

Bronchospirochætosis in the Lower Animals.—Mendelson in Siam has recently made the interesting observation of the occurrence of a form of bronchopulmonary spirochætosis in cats.

Complications.—Pneumonia and bronchopneumonia have been observed. Rhinitis has been noted. The disease may be complicated with tuberculosis and bronchomycosis.

Diagnosis.—This is based on the microscopic examination of the expectoration collected after rinsing the mouth and gargling with sterile water. The sputum may be examined fresh, using the dark ground illumination, or may be stained, using one of the many modifications of the Romanowsky stain, or nitrate of silver staining methods, such as the Fontana-Tribondeau, may be employed. The *Spirochæta bronchialis* is generally present in large numbers, while bacteria are very few.

Differential Diagnosis.—The acute type is often mistaken for influenza or malaria. The examination of the sputum, in which no Pfeiffer's bacilli are found, will distinguish the affection from influenza, and the examination of the blood will exclude malaria.

Cases of the subacute and chronic type presenting blood in the expectoration are generally diagnosed as phthisis. The examination of the sputum for tubercular bacilli will be always negative, and the animal inoculations will remain without effect. The ophthalmo- and cuti-reactions are negative in the great majority of cases. Occasionally, however, cases of mixed infections of tuberculosis and spirochætosis occur. From bronchomycosis the affection is distinguished by the absence of fungi; cases of double infection, however, bronchospirochætosis, and bronchomycosis, may at times be observed, though very rarely.

Spirochætosis is easily distinguished from endemic hæmoptysis by the examination of the sputum, which will show absence of the ova of *Paragonimus ringeri* Cobbold, and from bronchomycosis by the absence of fungi.

Prognosis.—The prognosis is favourable *quoad vitam*, but the disease may take a chronic course with anæmia and wasting.

Treatment.—In the acute cases all the symptoms as a rule disappear after a few days' rest in bed. Codeine ($\frac{1}{3}$ grain) and aspirin (5 grains) may be administered when the cough is painful and the patient complains of rheumatoid pains. In the subacute and chronic types of the disease, arsenic, introduced by Castellani in the treatment of the malady since 1906, gives good results. It may be administered by the mouth in the form of liquor arsenicalis or arsenious acid pills, or may be given subcutaneously in the form of cacodylates. Plaut and Galli Valerio recommend salvarsan. When the expectoration is profuse, glycerophosphates and balsamics are useful.

In certain cases tartar emetic, especially if combined with arsenic, is efficacious. The following formula may be used:—Tartar emetic, $\frac{1}{8}$-$\frac{1}{4}$ grain; liquor arsenicalis, 2-3 minims; codein, $\frac{1}{8}$ grain; glycerine, 1 drachm; syrup of tolu, 1 drachm; aquæ chloroformi, 1 drachm. One ounce to be taken three times a day well diluted.

Occasionally in cases with very dry cough, potassium iodide may be found useful; for instance:—Tartar emetic, $\frac{1}{8}$-$\frac{1}{4}$ grain; potassium iodide, 5 grains; bicarbonate of soda, 10 grains; glycerine, 1 drachm; syrup of tolu, 1 drachm; chloroform water, 1 ounce. One ounce to be taken three times a day well diluted with water.

Dalimier recommends injections of camphorated oil with gomenol in acute cases, and Liquor Fowleri in cinchona wine in chronic cases.

TROPICAL BRONCHOMYCOSES.

General Remarks.- Affections of the bronchi and lungs due to fungi are common in the tropics, though very little attention has been paid to them till recently. These conditions may be due to a variety of fungi, and may be classified in several groups:-

1. Due to fungi of the genus *Monilia* Persoon, 1797; *Oidium* Link, 1809; *Saccharomyces* Meyen, 1833; *Willia* Hansen, 1904; *Cryptococcus* Gilchrist and Stoker, 1896; *Coccidioides* Rixford and Gilchrist, 1898.
2. Due to fungi of the genus *Hemispora* Vuillemin, 1906.
3. Due to fungi of the genus *Nocardia* Toni and Trevisan, 1899; *Cohnistreptothrix* Pinoy, 1911.
4. Due to fungi of the genus *Aspergillus*, 1729; *Sterigmatocystis* Cramer, 1859; *Penicillium* Link, 1908; *Mucor* Micheli, 1729; *Rhizomucor* Lucet et Costantin, 1900; *Lichtheimia* Vuillemin, 1904.
5. Due to fungi of the genus *Sporotrichum* Link, 1809.

For description of above fungi the reader is referred to Chapters XXXVII., p. 967, XXXVIII., p. 978, and XXXIX., p. 1035.

The symptoms are somewhat similar, whichever fungus is the ætiological factor. In *mild cases* there are signs of slight bronchitis with muco-purulent expectoration in which the fungi are found. In *severe cases* the patient presents all the symptoms of phthisis, with hectic fever and hæmorrhagic expectoration.

Mild cases may get cured spontaneously: but they are often benefited by potassium iodide. We will describe in detail the forms of bronchomycosis which has been more completely investigated.

Bronchomoniliasis.

Synonyms.—Broncho-alveolar moniliasis (Castellani), Bronchoblastomycosis *pro parte*.

Definition.- An infection of the bronchial mucosa due to fungi of the genus *Monilia* Persoon, 1797.

Historical.—Since 1905 Castellani has published many cases, divisible into a mild type and a severe type of the disease, and has described several new species of *Monilia*. Castellani's work has recently been confirmed by Pijper, Pantin, and other observers. Magrou has recorded a case in France in 1916.

Geographical Distribution.—The disease is found all over the tropics, especially in places with a damp climate, such as Ceylon and the Malay Peninsula. The affection may be met with also in Europe and America, cases having been recently recorded by Pinoy, Iacono, and others.

Ætiology.—In Ceylon the malady is generally due to *Monilia tropicalis* Castellani, 1910. The same fungus may be found in cases coming from South India and the Malay States. It would appear that the fungus is the real cause of the disease, as no other ætiological agents, such as the tubercle bacillus, etc., are found. Moreover, when the patient gets better, the fungus becomes very scanty, or disappears completely. In some cases other species of the fungus may be observed, but it is doubtful whether all of these are really pathogenic. These species are *Monilia paratropicalis* Castellani, *M. pinoyi* Castellani, *M. guilliermondi* Castellani, *M. negrii* Castellani, *M. candida* Castellani, *M. nivea* Castellani, *M. insolita* Castellani, *M. pseudotropicalis* Castellani, *M. lacticolor* Castellani, *M. nitida* Castellani, *M. lactea* Castellani, *M. krusei* Castellani, and other monilias, among which *M. bethaliensis* Pijper. For the cultural characters of these species see p. 1079.

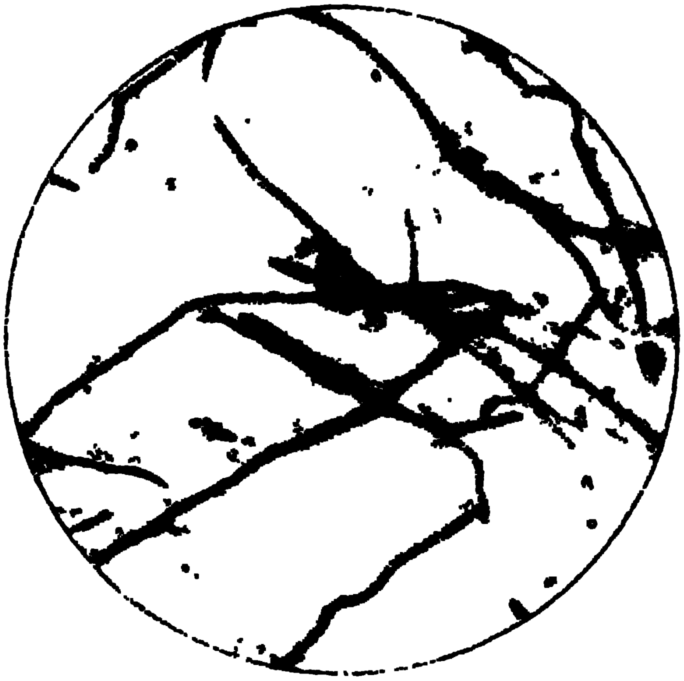

FIG. 773.—FUNGUS FROM A CASE OF BRONCHOMYCOSIS (UNDETERMINED)

The infection may take place from man to man, and also probably by the fungi living saprophytically in nature. Monilia-like fungi are extremely common in Ceylon in tea-dust, and it is very probable that the so-called 'tea-factory cough' is a type of moniliasis.

Symptomatology.—A mild and a severe type of the malady may be distinguished. In the *mild type* the general condition of the patient is fairly good, there is no fever, and he simply complains of cough. The expectoration is muco-purulent and very often scanty, and no blood can be seen. The physical examination of the chest will reveal only a few coarse râles or absolutely nothing. The condition may last several weeks or months, and may get cured spontaneously, or, continuing, may turn into the severe type. The *severe type* closely resembles phthisis; the patient becomes emaciated, there is hectic fever, muco-purulent and bloody expectoration. Occasionally true hæmoptysis occurs, a teaspoonful or more of bright blood being spat up at a time. The physical examination of the chest may show patches of dulness, fine crepitations, and pleural rubbing. This type is often fatal. Between these two extreme types there are of course cases of intermediate severity, apyretic or with subcontinuous and continuous fever, and more or less marked bronchial and broncho-alveolar symptoms.

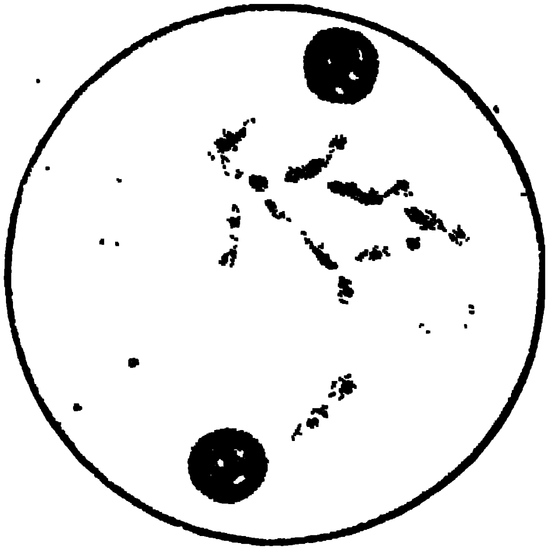

FIG. 774.—SPUTUM IN BRONCHOMONILIASIS (SEVERE CASE).
(From a preparation stained with methylene blue.)

Diagnosis.—The diagnosis of moniliasis is based on finding the fungus in the sputum. It is absolutely necessary that this should be collected in sterile petri dishes and examined as soon as possible, as sputum exposed to the air becomes contaminated with all sorts of fungi in the tropics. In fresh preparations of the expectoration spore-like, roundish, or oval cells 4 to 6 μ are seen, often presenting a double contour, alone or more rarely with some mycelial articles. The fungus is Gram-positive.

To identify the fungus cultural researches are necessary. A particle of the sputum is smeared on maltose or glucose agar plates; after two or three days white, rather large, roundish colonies appear, easily distinguishable, even macroscopically, with a little practice, from the colonies of cocci and other bacteria. The fungus colonies are further investigated by inoculating maltose agar, ordinary agar, gelatine, serum, and a set of sugar broths. All the species of *Monilia* found in our cases grow well on ordinary agar, but much more abundantly on maltose and glucose agar, especially if slightly acid.

On these media the growth, which is generally white with a smooth surface when young, slightly crinkled when old, is composed practically of globular, yeast-like cells, while in the water of condensation globular cells and mycelial elements are found together. A little mycelium may, however, be found also occasionally in the growth on the slope. On serum all the strains produce at first a white growth, but some, later on, induce a peculiar brownish-black discoloration of the medium round the growth. Most species do not liquefy the medium.

On *gelatine* all the species grow fairly well; a few, including *Monilia albicans*, produce liquefaction of this medium. In milk some do not produce either acid or clot, others produce a temporary or permanent acidity, others clot the milk or peptonize it. The reactions in the various sugar broths are important, and in association with the behaviour of the fungi on serum, gelatine, and milk, give the data on which to differentiate the various species (*vide* p. 1081).

Differential Diagnosis.—Primary bronchomoniliasis, as described in this chapter, should be distinguished from the secondary bronchomoniliasis occasionally met with in cachectic patients suffering from cancer, diabetes, tuberculosis, etc. In such cases there is generally thrush of the oral mucosa, and the thrush *Monilias* spread to the pharynx, larynx, and bronchial mucosa, while in primary bronchomoniliasis the oral mucosa is not, as a rule, affected.

From pulmonary tuberculosis the condition is distinguished by the absence of the tubercle bacillus in the sputum and the negative animal inoculations. Cases of mixed infection, however—tuberculosis and moniliasis—are occasionally met with, the sputum containing both the tubercle bacillus and the *Monilia* fungi.

From bronchospirochætosis it is recognized by the absence of spirochætes, though occasionally cases of mixed infection occur; from endemic hæmoptysis by the absence of the ova of *Paragonimus ringeri* Cobbold.

Prognosis.—The cases of a mild type may recover spontaneously or under appropriate treatment. Those of the severe type usually end fatally.

Treatment.—Mild cases and those of medium gravity respond often to potassium iodide (gr. x. to xx.) given well diluted in water or milk three times daily. When potassium iodide causes severe symptoms of iodism, saiodin in the same doses (in cachets) may be administered. In the cases of the severe type we have seen no improvement from the many different treatments administered. Potassium iodide, however, should always be tried also in these cases, as well as balsamics. The diet should be nourishing; hypophosphites and glycerophosphates may be tried to keep up the strength of the patient, as in phthisis.

Broncho-Oidiosis.

Synonyms.—Bronchial oidiomycosis, Broncho-endomycosis.

Historical.—Cases have been described by Blanchard, Chantemesse and Vidal, Linossier, Pinoy, Castellani, and others.

Geographical Distribution.—The same as bronchomoniliasis.

Ætiology.—The following species of the genus *Oidium* Link have been found in cases of bronchitis, although it is doubtful whether they are all pathogenic:—

Oidium lactis Link, including *O. lactis A*, a variety described by Linossier.
Oidium matalense Castellani.
Oidium rotundatum Castellani.
Oidium asteroides Castellani.

For description of these fungi the reader is referred to Chapter XXXIX., p. 1093.

Symptomatology.—This is identical with that of bronchomoniliasis, and two types may be distinguished: the mild type and the severe one.

Prognosis.—Favourable in a certain number of cases but cases are met with which do not respond to any treatment and terminate fatally.

Diagnosis.—This can be made only by cultural methods.

Treatment.—Potassium iodide should be tried in all cases, but its action in a large number of them is very uncertain or completely negative. It may be given in combination with glycerophosphates. A change of climate is often useful.

Bronchohemisporosis.

General Remarks.—This bronchomycosis has been described by Castellani. The fungus found so far is *Hemispora rugosa* Castellani, a description of which will be found in Chapter XXXIX., p. 1108.

Symptomatology.—The symptoms are very similar to those seen in bronchomoniliasis, and a mild and a severe type of the affection may be distinguished. In the mild type the general condition of the patient is good, there is no fever, and he simply complains of cough. The expectoration is muco-purulent and does not contain blood. The physical examination of the chest is negative or reveals only a few râles. The *severe type* closely resembles phthisis. The patient becomes emaciated, there is hectic fever, and the expectoration may be bloody. The physical examination may reveal patches of dulness, fine crepitations, pleural rubbing.

Complications.—The affection may be complicated with a tonsillitis, caused by the same fungus and characterized by the presence of yellowish or greyish patches: at other times the tonsillitis is the primary lesion.

Treatment.—Potassium iodide seems to be more efficacious in this condition than in bronchomoniliasis. It should be given in 10-grain doses, well diluted in water or milk, twice or four times daily. Glycerophosphates and balsamics are useful.

Tea-Factory Cough.

This affection described by Castellani in 1910, is common in Ceylon. It is probably a form of broncho-mycosis. Coolies working in tea-factories are occasionally observed to deteriorate in their general health, losing flesh and becoming easily tired; at the same time they develop a cough with muco-purulent expectoration. The physical examination of the chest reveals nothing except occasionally a few coarse râles. If these coolies are taken away from the factory and sent to work in the fields, all the symptoms slowly disappear.

A similar affection may be observed in tea-tasters. Tea-tasters, in order to judge of the quality of teas, not only taste infusions, but frequently fill their hands with the leaves and bury their noses in them, snuffing them up; in this way a certain amount of tea-dust enters their nasal cavities, and with the tea-dust the micro-organisms which are found in it. According to the researches of one of us, tea and tea-dust in Ceylon contain:—

1. Fungi of the genus *Monilia* constantly.
2. Fungi of the genus *Oidium* occasionally.
3. Fungi of the genus *Aspergillus*, *Sterigmatocystis*, and *Penicillium* frequently.
4. A peculiar *streptococcus*, somewhat different from *S. pyogenes*, frequently.

It is interesting to note that such germs are very rare or absent in samples of tea examined in England. The same organisms may be found, in Ceylon, in nasal cavities of tea-tasters: in their expectoration the *Monilia*-like fungi are practically constant, the *streptococci* very frequent, while *Aspergillus* and *Penicillium* fungi are rare. Guinea-pigs in whose nostrils tea-dust is daily insufflated for months develop a broncho alveolar moniliasis.

Bronchial Aspergillosis.

Synonyms.—Broncho-alveolar aspergillosis, Aspergillar pseudo-tuberculosis, Pneumomycosis of aspergillar origin.

Definition.—A form of bronchitis and broncho-alveolitis due to fungi of the genus *Aspergillus* Micheli, 1729, and *Sterigmatocystis* Cramer, 1869 (p. 1026).

Historical.—The condition has been studied by Virchow, Lichtheim, Dieulafoy, Chantemesse, Widal, one of us, Wise, and others.

Climatology.—The geographical distribution of the disease seems to be cosmopolitan. It is very common in certain parts of France, and one of us has seen two cases in the Balkans. In the tropics we have seen some cases in Ceylon and Tropical Africa, and Wise has reported a case from British Guiana.

Ætiology.—The condition is due to fungi of the genus *Aspergillus* Micheli and *Sterigmatocystis* Cramer. It is common especially in people who have to handle various grains on which spores of those fungi are often found. In France it is extremely frequent among pigeon-breeders (*gaveurs de pigeons*), who fill their mouths with grain and blow it into the mouths of the pigeons. Of the two cases observed by us in the Balkans, one was apparently due to *Aspergillus fumigatus* Fresenius, the other to *Sterigmatocystis nigra* Cramer.

It is probable that the deleterious effects caused by the fungi are due not only to a mechanical irritative action, but also to toxins secreted by the fungi.

Morbid Anatomy.—The lungs, and occasionally the liver, kidneys, and other organs, may show a type of pseudo-tuberculosis characterized by the presence of numerous mycotic tubercular-like nodules.

Symptomatology.—The presence of the fungi in the bronchi, when in smal amount, may not give rise to any symptom. When the infection is heavy, symptoms of bronchitis with muco-purulent, and occasionally bloody, expectoration are present, and in severe cases the patient may have hectic temperature, with sweatings and great wasting.

Diagnosis.—This is based on finding the fungus. It is to be noted that in the sputum as a rule only mycelial threads are found, and cultivations are therefore necessary.

Prognosis.—Mild cases often recover, but in severe cases with bloody expectoration the prognosis is bad.

Treatment.—A change of climate and, when the condition is brought about by certain occupations, a change of occupation is very beneficial. Potassium iodide (gr. xv. to xx.) may be administered.

Bronchial Penicilliosis.

One of us has observed cases of bronchitis and broncho-alveolitis due to fungi of the genus *Penicillium* in the tropics and one in the Balcanic zone. The fungus isolated from the last case was *P. crustaceum* Linnæus.

The symptomatology, diagnosis, and treatment are the same as in Bronchial Aspergillosis.

Bronchial Mucormycosis.

Cases of bronchitis caused by fungi of the genus *Mucor* Micheli, 1729, *Lichtheimia* Vuillemin, 1904, *Rhizomucor* Lucet and Costantin, 1900, *Rhizopus* Ehrenberg, 1820, may be met with, but are of rare occurrence. The symptomatology is the same as that of Bronchial Aspergillosis. We have seen a case in the Balcanic zone due to *Mucor mucedo* Linnæus. For description of the fungi see p. 972.

Bronchial Sporotrichosis.

A few cases have been described of a bronchitis due to fungi of the genus *Sporotrichum* Link, 1809

Undetermined Bronchomycosis.

One of us has described cases of bronchomycosis due to fungi which have not yet been classed.

PULMONARY NOCARDIASIS.

Synonyms.—Pulmonary streptothromycosis, Pseudo-tuberculosis.

Definition.—Pulmonary nocardiasis is an infection of the lung, and usually other organs, with a species of the fungal genus *Nocardia* Toni and Trevisan, in which the signs and symptoms more or less resemble those of phthisis.

Historical.—In 1897 Flexner described this disease, isolating the causal organism, which he named *Streptothrix pseudotuberculosa* Flexner, 1897. In the same year Buchholz found a similar case in Berlin, and Scheele and Petruschky described a third at the Wiesbaden Congress. In 1902 Birt and Leishman met with a case in a soldier, and since then similar cases have been recorded by Foulerton, by Roger, Bory, and Sartory in 1909, and have been seen by ourselves in Ceylon, the Balcanic zone, and the Anglo-Egyptian Sudan, and by Pijper in South Africa

Climatology.—The disease occurs in the Temperate and Tropical Zones, in the New and the Old World, and may therefore be widespread.

Ætiology.—The causal agents appear to be varying species of nocardia—thus, for example, Flexner's case was caused by *Nocardia pseudotuberculosa* (Flexner, 1897); Birt and Leishman's case by *Nocardia leishmani* Chalmers and Christopherson, 1916; Scheele and Petruschky's case by *N. gedanensis* (Scheele and Petruschky, 1897); and Foulerton's organism by *N. foulertoni* Chalmers and Christopherson, 1916; while Roger, Bory, and Sartory's organism is called *N. pulmonalis* (Roger, Bory, and Sartory, 1909). Very commonly these fungi are present in the sputum as acid-fast rods which may or may not appear in branched form. When present in rod-like forms they give rise to an appearance somewhat resembling the tubercle bacillus. Other species of nocardia, also found in sputum, may not be acid-fast, and these are more easily recognized.

Morbid Anatomy.—As a rule the appearances found post-mortem are not unlike that of tuberculosis. There is consolidation, necrosis, and cavity formation in the lung, with or without the signs of caseous pneumonia or of calcareous deposition, or there may be small cirrhotic nodules scattered through the lung. There may also be nodules in the liver, spleen, peritoneum, and lymph glands, and there may be chocolate-coloured exudate into the pleural or peritoneal cavities. This exudate may be odourless or fœtid in odour. The fungus can be easily found in these pseudo-tubercles.

Symptomatology.—In general it may be stated that the symptoms resemble those of phthisis, and as such the disease is usually recognized. Usually there is fever, cough, a muco-purulent sputum containing blood at times and showing acid-fast rods resembling the *Bacillus tuberculosis*, but careful search may reveal a few elongate or branching forms. The physical signs are those of chronic broncho-pneumonia, with or without cavity formation, and with or without those of pleural effusion. The liver and spleen are often enlarged. The cases usually go from bad to worse, and end in death.

Diagnosis.—Many of these cases are diagnosed as *pulmonary tuberculosis* at the present time. The correct diagnosis can only be established by a careful examination of the sputum, by microscopical and bacteriological methods, including the culture of the organism.

The differential diagnosis has to be made from *phthisis* and *liver abscess*.

It may be distinguished from phthisis by the recognition of the beaded branched organism in the sputum and the culture of it therefrom.

In cases giving a history of dysentery and exhibiting enlargement of the liver, fever, and a purulent chocolate coloured effusion into the pleural cavity, the diagnosis can only be effected by finding the fungus and by the absence of any pus in the liver. In such cases the dysenteric amœba may be present in the fæces.

For the morphological and cultural characters of the species of nocardia see Chapter XXXIX., p. 1040.

Prognosis.—So far the prognosis is very bad, as all known cases have died.

Treatment.—Iodide of potash in large doses may be tried or a vaccine made from the patient's causal organism.

Prophylaxis.—Nothing whatever can be said on this part of the subject.

CHAPTER LXXXII

DISEASES OF THE CIRCULATORY SYSTEM

General remarks—The blood—Blood puzzles—Anæmia and allied conditions—Leukæmia—General dropsy—The heart—The vessels—The spleen—The bone-marrow—References.

GENERAL REMARKS.

In this chapter we merely make a *few allusions* to some points of tropical importance with regard to the blood and the organs which produce and circulate it. The subject is not merely a large one, but is of great importance in the tropics, and our few remarks are merely of an introductory nature.

THE BLOOD.

We in no way intend to enter at all fully into an important study of the blood, which is to be found in detail in the special books devoted to its elucidation; but we desire, in the briefest manner possible, to present to the reader a few remarks which have a direct bearing upon the various references which we have made from time to time in the preceding chapters with regard to it.

The Erythrocyte.

In embryonic life the first sign of the blood cell is to be found in those mesoblast cells of the vascular area which contain hæmoglobin and are called megaloblasts, and to these are added later similar cells without hæmoglobin and found in the liver. In post-embryonic life these cells are found in the red marrow lying at the ends of long bones and in flat bones, and normally do not appear in the circulating blood, but are the parents of the normoblasts, which are commonly found in the blood after mid-term of fœtal life and in the red bone-marrow of post-embryonic existence.

These normoblasts, multiplying by mitosis, are the source of the erythrocyte, which alone is the proper denizen of the circulating blood.

An erythrocyte, according to von Schilling-Torgau, is saucer-shaped, with a thickened edge, and consists of:—

1. An ectoplasmic cell *membrane*, inside which lies the endoplasm, of which the peripheral portion is condensed to form the *endoplasmic capsule*, which is Weidenreich's cholesterin-lecithin membrane, inside

which lies the *stroma*, in the form of a network of protoplasmic threads and nodes, which contains the hæmoglobin, and in the saucer-shaped corpuscle forms a cap over the archoplasm, which lies just over the concavity of the saucer.

2. The *archoplasm* is composed of a central clear hæmoglobin-free area, and is composed of a *glassy body*, which is rest material, and which in ordinary cells forms the achromatic spindle in mitosis. Excentrically placed and surrounded by the glassy body lies the *capsule corpuscle*, near which lie two sharply defined bodies embedded in a substance which may contain a vacuole. These are the *centrioles*.

3. The *blood plate* is the metamorphosed nucleus of the normoblast, which lies excentrically on one side of the archoplasm. It is easily extruded in making the blood film, and gives rise to the blood platelets which are so well known. Its peculiar appearance is possibly due to physiological modification during mitosis of the normoblast.

4. *Meve's plastokonten* are granular bodies of unknown nature scattered through the erythrocyte, but mostly seen near the archoplasm.

As we shall see later, these various parts of the erythrocyte are the explanation of the intracorpuscular blood puzzles and the origin of the numerous intracorpuscular pseudo-parasites of many observers.

The red corpuscles number some five millions in a healthy male, and some four and a half millions in a healthy adult female under the climacteric age, but there are physiological increases of these numbers in infancy, by cold and at high altitudes, while race has but little influence.

Pathologically they can be increased by mechanical means—*e.g.*, the concentration of the blood caused by diarrhœa, sweating, vomiting, and polyuria, or by heart disease. They can also be increased in toxic conditions and in polycythemic splenomegaly. They may be decreased by any mechanical, toxic, or parasitic cause which induces blood destruction.

The normoblasts of the bone-marrow may accidentally occur in the normal circulating blood as an isolated form, but in numbers they indicate that there is an abnormal demand for erythrocytes—as, for example, after a hæmorrhage. A normoblast is about the same size as an erythrocyte (7·5 microns), but contains a rounded nucleus composed of a nuclear membrane containing dense chromatin and measuring about 4 microns.

The megaloblasts may be found in the circulating blood if some toxin is attacking the bone-marrow. They are usually of large size (20 microns), but this is not their characteristic, which is the large nucleus measuring some 10 microns and containing loosely arranged hromatin. The nucleus may undergo the usual changes, and the egaloblast become a megalocyte.

Microblasts are small cells or abnormal normoblasts or megaloasts.

The Leucocyte.

In post-embryonic life the home of the leucocyte or colourless blood cell is the bone-marrow. They may be divided into the hyaline cells or lymphocytes, which are the least differentiated cells, both ontogenetically and phylogenetically, being the first to appear in the embryo and in the lower animals, and the granular cells or leucocyte *sensú stricto*, which are more highly evolved cells.

It is usual to consider the large lymphocytes, the small lymphocytes, the large mononuclears, and the transitional cells, as all belonging to the same denomination. According to Heidenhain, there is a tendency on the part of the centrosome to reach the centre of the lymphocyte, being pulled thereto by cytoplasmic radii. It is, however, prevented from assuming this position by the nucleus, which succeeds in this obstruction in the case of the small and large lymphocyte, because there is insufficient cytoplasm; but in the case of the large mononuclear it pushes the nucleus to one side, and in the case of the transitional it so indents the nucleus that it attains in both cases the central position. Thus the small lymphocyte by growth can become the large lymphocyte, from which are descended the large mononuclear and the transitional, which may, therefore, be reckoned as a single type in making a differential count.

The small lymphocyte is about the size of an erythrocyte, but somewhat smaller; it possesses a rounded or slightly indented nucleus, colouring deeply with basic stains, and surrounded by a very slight amount of cytoplasm, which shows a reticulum with basophile granules as the nodal points. There are also some azurophile granules.

The large lymphocyte is larger, reaching to 20 microns, and is characterized by a central roundish or slightly indented nucleus, which contains less chromatin than in the small variety. There is more abundant cytoplasm, which does not stain so deeply, but contains the same reticulum and Wolff's azurophile granules.

The large mononuclear leucocyte possesses an excentric nucleus relatively poor in chromatin, surrounded by a larger amount of cytoplasm, with the usual reticulum and azurophile granules.

The transitional cell has its nucleus indented into a horseshoe or sometimes twisted. Lymphocytes and myeloblasts may contain fuchsinophile granules called Schridde's granules. The true leucocytes or granular white cells are classified according to their granules into neutrophile, eosinophile, and basophile. Their parents are the myelocytes of the bone-marrow, which are cells of large size possessing rounded pale-staining nuclei and the granules typical of the particular leucocyte to which they are to give rise.

The most primitive form is the eosinophile leucocyte which is so common in lower animals. It probably has a secondary home in connective and lymphoid tissue. They are characterized by their large refractile granules, which have an affinity for acid stains and a twisted, trilobed, or dumb-bell-shaped nucleus.

The polymorphonuclear neutrophile leucocyte is generally called by the first portion of its name. It varies considerably in size, and is characterized by a lobulated nucleus in which the lobules vary in number, but however separate they may appear, are always connected by fine threads. It is upon this lobulation that the *Arneth count* is based, and the form of the nucleus can be explained in the same way as in the transitional (*vide supra*).

The basophile leucocyte or mast cell has a trilobed nucleus poor in chromatin and a cytoplasm containing basophile granules. The corresponding myelocytes may under abnormal circumstances be found in the circulating blood, and even at times the pro-myelocytes, which resemble myelocytes, but possess a basophile cytoplasm with a few neutrophile granules. More rarely cells with a large rounded nucleus containing a fine chromatinic network and three to four nucleoli, and surrounded by an intensely basophile cytoplasm, may be seen. These are Naegeli's myeloblasts.

Under pathological conditions such as anaemia, with jaundice and leucocythemia, a few plasma cells may be seen in the blood. They are triangular, with an excentric nucleus and a markedly basophile granular cytoplasm.

The number of white cells varies from time to time from about 5,000 to 9,000 per cubic millimetre, but the average is about 7,000, or one to every 700 erythrocytes.

lowing Gulland and Goodal the average differential count is as follows:-

	Per Cent	
Polymorphonuclear neutrophile leucocytes ..	70	Average.
Small lymphocytes	20	
Large lymphocytes	5	
Eosinophile leucocyte . ..	4	Maximum.
Basophile leucocytes	1	

The *Arneth count* formulated in 1904 is based upon the number of lobules in the nucleus of 100 polymorphonuclear or 100 eosinophile leucocytes. Class I. contains those with a single rounded or indented nucleus, and would include any neutrophile myelocyte which happened to be present. Class II. has two, Class III. three, Class IV. four, and Class V. five lobules. The numbers in Classes I. and II. added together give the Arneth index, and in Classes I., II., and half III., give the Bushnell-Trenholtz index. Arneth subdivided each class into smaller groups by the indentations and the character of the loops and lobes, but these are not now considered. He restricted his counts to polymorphonuclears, but to-day eosinophile leucocytes are also considered. In counting it is wise to follow Chamberlain and Vedder, and to consider as one, lobules with a distinct isthmus, and in cases of doubt to place the number in the higher class. Arneth considered that the youngest cells were those in Classes I. and II., and that those in Class V. were the oldest, while Classes III. and IV. are believed to be adult. These views have been contested, as has Pottenger's opinion that the phagocytic power increases from Class I. to Class IV., and falls in Class V. When the numbers in Classes I. and II. are increased above normal it is called 'a shift to the left,' and the reverse 'a shift to the right,' terms which have been used in Chapter IV. According to Arneth, a shift to the left is evidence of lower resistance on the part of the patient to a disease. This count has been tested in the tropics by Chamberlain and Vedder, Macfie, Breinl, and others, as has been set forth on p. 75.

A few examples may be given as follows:—

ARNETH COUNT.

Kind of Leucocyte.	*Nature of Observation.*	*Observer.*	*Class I.*	*Class II.*	*Class III.*	*Class IV.*	*Class V.*	*Arneth Index.*
Polymorphs	Normal in Europe	Arneth	5	35	41	17	2·0	40·0
Polymorphs	Normal in America	Kagan	5	19	46	25	5·0	24·0
Polymorphs	Normal Americans in Philippines	Chamberlain and Vedder	13·3	32·9	37·2	14·6	2·0	46·2
Polymorphs	Normal Philippinos	Chamberlain and Vedder	27·5	38·3	25·8	7·5	0·9	65·8
Polymorphs	Normal limits	Simon	4-9	21-47	33-48	9-23	2-4	25-56
Eosinophiles	Normal in Europe	Arneth	11	69	19	1	--	80

Von Schilling-Torgau suggests a modification, which is to classify the neutrophiles as myelocytes, myelocytes with indented nucleus, polymorphs with rod-shaped nuclei, polymorphs with segmented nuclei. It is said that this simple method gives the same results as the Arneth count.

The Arneth count is being used at present in tropical work, but its value is still *sub judice*.

The leucocytes vary in number under physiological and pathological conditions:—

Leucopenia, or diminution in their numbers, may occur in physiological conditions such as hot or cold baths, or in pathological conditions such as certain protozoal infections, malaria, trypanosomiases, and kala-azar; in bacterial infections such as enteroidea, undulant fever, tuberculosis, and influenza, or in severe toxæmias of any kind. The leucopenia is usually polymorphonuclear, but in fevers there is a diminution of eosinophiles.

Leucocytosis, or increase in their numbers, may occur in physiological conditions such as infancy, pregnancy, digestion, and exercise, and there is a terminal or agonal leucocytosis before death. In pathological conditions a leucocytosis due to polymorphonuclear leucocytes may occur in septic or inflammatory conditions, many fevers and toxæmias, after hæmorrhage, and with malignant disease.

Lymphocytosis may be relative when there is a relatively high percentage of lymphocytes and low of polymorphs, with no increase in the total number of white cells, or absolute when the total number of white cells as well as of lymphocytes is increased. The former occurs in protozoal infections such as malaria, amœbic dysentery, etc., and the latter in leukæmia, etc.

Eosinophilia, or increase in the eosinophile leucocytes, occurs in helminth infections, in skin diseases, in asthma, in toxic states, and in myelocythæmia.

Basophilia occurs in myelocythæmia and staphylococcal infections, but in the latter only slightly.

Blood Platelets.

These are probably derived from the erythrocytes, and may possibly not be present in normal circulating blood, but formed in preparing the films. Their clinical value is not absolutely certain. They are said to number about 300,000 per cubic millimetre in health. They are colourless, refractile, discoidal bodies, some 1-3 microns in diameter, having a great tendency to adhere together and having an affinity for basic dyes.

Hæmoconia.

These are colourless refractile bodies, 0·5-4 microns in diameter, which do not colour with ordinary stains and are of unknown origin and function, though they may be fat particles, as shown by Neumann.

BLOOD PUZZLES.

Blood puzzles consist of bodies which from the first have been recognized as such or in other instances have been thought to be parasites.

It is difficult to give a systematic account of these bodies, but, following Balfour, we may classify them as follows:—

A. Heterogenetic:—Not in the blood.
B. Autogenetic:—Actually in the blood.
    I. Found in fresh blood:—
        (*a*) Erythrocytic.
        (*b*) Leucocytic.
    II. Found in stained blood:—
        (*a*) Erythrocytic.
        (*b*) Leucocytic or lymphocytic.

Heterogenetic.

These are external or adventitious, and may be divided into:—

I. Those belonging to the glass slide.
II. Those belonging to cleaning or drying materials.
III. Those coming via the air.
IV. Those coming from the skin.
V. Those coming from the intestines.

The Glass Slide.—Everyone is well aware of the peculiar marks which may appear on old glass slides, and which retain the stain, thus giving rise to pseudo-trypanosomes, yeasts, and many other forms.

Perhaps the most interesting of these are the 'X bodies' (Horrocks and Howell) which appear in Romanowsky films as roundish bodies, with a small blue circular centre surrounded by four or more faint concentrically arranged capsules, and which Chamberlain and Vedder have shown to be artefacts present in the glass slide.

Cleaning and Drying Materials.—Cotton fibres may be introduced from a cloth in cleaning slides. Blotting-paper, if used twice for drying blood slides, may introduce one kind of blood into another or bacteria into a blood film.

The Air.—Insect scales, plant hairs, animal hairs, yeasts, and pollen grains, may all be introduced into blood films from the air, and especially multiseptate fungal spores.

The Skin.—Pieces of dirt, epithelial scales, and bacteria, may come from the skin.

The Intestine.—In obtaining films during a post-mortem or from an animal which has been shot there is danger of contamination of the blood with spirochætes and other organisms from the intestine.

Autogenetic.

These are bodies which are really in the blood, whether natural products or artificial productions.

Fresh Blood—ERYTHROCYTE.—In anæmic blood the erythrocytes become deformed, forming oval, pear-shaped, tailed, or irregular bodies called poikilocytes, allied to which are the peculiar chain-like, droplet-like, and filament-like bodies figured by Nuttall and Balfour as produced when taking films in high air temperatures. Some of them may be mistaken for parasites, but only by beginners.

A crenation seen in a deformed or in an ordinary corpuscle may in certain focal planes look like a malarial parasite.

Vacuoles have clear-cut margins, do not move, do not possess pigment, and are quite clear, yet they give rise to trouble, and may be mistaken for piroplasma or for malarial parasites.

The glassy body mentioned above, when easily visible, is often mistaken for a parasite, and is probably the explanation of the 'maraglianos' or dehæmoglobinized spots which have been described, as well as of such pseudo-parasites as those mentioned by Balfour as being described by Foran and Breeze. The dark spot mentioned as being visible in the maraglianos may be the centrosome.

A granule from a leucocyte or a blood platelet lying on an erythrocyte may simulate a parasite.

LEUCOCYTE.—The leucocyte, especially the eosinophile, is responsible for the free granules, and worse for the free or attached wavy process, which is apt to be mistaken for a spirochæte, especially when a beginner is using the dark-ground illumination.

Stained Blood.—ERYTHROCYTE.— When the glassy body swells it gives rise to pale large red blood cells 15-50 microns in diameter, which are the half-moon-shaped or sickle-shaped corpuscles of Stephens and Christophers.

The hæmolyzed stroma is the cause of the shadow corpuscles, and polychromatophilia is due to diffuse colouring of the reticulum, while the punctate form is due to the nodes being especially tinted.

Schüffner's dots are caused by the coloration of nodes of the reticulum in older cells, while pathological karyolysis of the nuclear plate may be the cause of the Howell-Jolly bodies and the ring-shaped bodies of Cabot, and perhaps the so-called *Paraplasma flavigenum* is due to the same cause.

The capsule corpuscle may be the origin of Arnold's nucleoids, Schmauch's bodies, Heinz's corpuscles, and many pseudo-parasites.

A blood platelet lying on an erythrocyte may resemble a malarial parasite.

LEUCOCYTE.—The puzzles in connection with the leucocyte or lymphocyte may be divided into.—

1. Extranuclear.
2. Intranuclear.

Extranuclear.—Kurloff's bodies seen in the large lymphocytes, especially in guinea-pigs, are large vacuoles with a homogeneous structure, and may be a secretion, but have been considered to be parasites. They take a purplish or reddish colour with Giemsa's stain.

Oval or round rings may possibly be connected in some way with the area around the centrosome. Ferrata's plasmosomes are small metachromatic bodies which are thought to indicate retrogressive changes: they may be derived from the chromatin of the nucleus.

In 1912 Castellani described extranuclear non-parasitic bodies in leucocytes. They take, with Giemsa's stain, a blue colour, almost constantly show dots of chromatin, and measure 2-6 microns in diameter. They also occur free in the liquor sanguinis, and are by him considered to be degenerate red blood cells engulfed by the leucocyte.

Intranuclear.—The nucleus of the mononuclear leucocyte is apt to undergo changes and to show bodies with a blue cytoplasm, with or without chromatinic spots, which look very like parasites, as also described by Castellani in 1913.

BLOOD PARASITES.

The blood may contain a number of parasites—*e.g.*, the malarial parasites, the spirochætes, the trypanosomes, the kala-azar parasites—as well as certain worms—*e.g.*, the Microfilariæ, *Schistosoma hæmatobium*, *S. japonicum*, and *S. mansoni*.

ANÆMIA AND ALLIED CONDITIONS.

Anæmia is common, being generally associated with ankylostomiasis, malaria, kala-azar, chronic dysentery, or in women repeated pregnancies and prolonged lactation. It is especially common among coolies working on estates. The treatment is to remove the causal agent, and then to administer the old mixture of sulphate of iron, sulphate of magnesium, and nux vomica to the poorer classes, while intramuscular injections of iron alone or combined with arsenic or sodium glycerophosphate are more scientific and more suitable for the better classes.

Chlorosis is rare, but we have seen cases in Europeans and in better-class native girls.

Paranæmia Tropicalis.

Everyone residing in the tropics is acquainted with the pallor which is visible in the faces of many European residents who, apparently, are in good health. An examination of the blood fails to reveal any marked diminution in the red cells or hæmoglobin, or, at all events no such reduction as would be compatible with the pallor. We have used the term paranæmia to indicate the condition.

In Chapter III., section Effects on the Blood (p. 75), we have shown that this apparent anæmia has been carefully studied by W. M. Strong, who considers that this pallor is really caused by the deposition of pigment in the epidermis. This pigment renders the skin opaque to the red rays contained in sunlight, and hence the colour reflected therefrom appears to the eye white.

In diagnosing this condition care must be taken to exclude true anæmia by a count of the red cells in the blood and an estimation of the hæmoglobin.

De Langen believes there are real differences between the blood of Europeans in the Tropics and at home: a shift to the left of Arneth's count, diminution of cholesterin, increase in blood sugar. He attributes to the hyperglycæmia the low fever so often found in the Tropics.

LEUKÆMIA.

Leucocythemia cannot be said to be very rare, at all events in our experience, and may be either spleno-medullary or lymphatic in type. It is most necessary to remember the possibility of the occurrence of this disease, and to make it a rule to examine the blood microscopically before performing splenic or hepatic puncture in cases of splenomegaly.

Pseudo-leukæmia and **Banti's disease** are also known.

GENERAL DROPSY.

Cases of general dropsy not due to heart or renal disease may be caused by beri-beri or ankylostomiasis.

THE HEART.

Heart disease has not been carefully studied by modern methods in the tropics, but cases of heart-block due to malaria and syphilis have been recorded by us.

Pericarditis and *endocarditis* are not as common as in other regions, probably because rheumatism is rare, and therefore they are due to such other causes as gonococcal infection, etc. Atrophies of the heart, especially brown atrophy, are quite common as the result of some general disease. Heart-block is rare, but has been met with. Rupture of a perfectly normal myocardium, the pericardium being intact, is recorded by Herzog as due to fracture of the second, fourth, and fifth ribs.

Tropical Heart.

Under this heading MacLeod has described the conditions of palpitation and dyspnoea on going up hills met with in persons who have resided long in the tropics. He assigns this to degeneration of the heart, brought on by the heat and by the exceptional work which it has to do owing to the changes in the circulation which result from the high temperature of the tropics. He considers this to be the basis of the syncopal form of heat exhaustion. Ernest Black believes that the condition is associated with subnormal blood coagulability, and recommends the administration of calcium salts. The salt he prefers is calcium lactate, which he gives in 10-grain doses. He points out that calcium salts are essential for the systole of the heart as well as for the normal cogulability of the blood, and refers their beneficial action to this property. He considers that citric acid or its salts should be avoided when calcium salts are administered, as they increase the calcium excretion.

THE VESSELS.

Atheromatous degeneration of the arteries is quite common, and aneurysm is found, generally affecting the thoracic aorta, while varicose veins and varicocele are usual, and, associated with hypertrophy of the heart, are very common among rickshaw coolies.

Thrombosis is often met with as the result of typhoid fever and other diseases, and we have seen thrombosis of a coronary artery with myomalacia cordis or aneurysm of the heart.

THE SPLEEN.

The spleen is affected in malaria, kala-azar, relapsing fever, etc., s already described. Capsulitis is very commonly met with in post-mortems, but splenic abscess is, in our experience, rare, and may be of entamœbic origin. Infarcts and tuberculosis are, however, not so rare, and spleno-medullary leukæmia, as has been mentioned above, is not very rare. Rupture of the enlarged malarial spleen has already been mentioned, and may cause death within a few minutes, or the patient may live for several hours.

BONE-MARROW.

The importance of the bone-marrow is often overlooked in the tropics. It requires especial study in anæmias, kala-azar, and malaria.

CHAPTER LXXXIII

DISEASES OF THE LIVER AND PANCREAS

General remarks—Tropical liver—Amœbic abscess of the liver—Opisthorchiosis—Clonorchiosis—References.

GENERAL REMARKS.

DISEASES of the liver and pancreas are of common occurrence in the tropics. *The liver* may be affected in the course of tropical fevers, especially in malaria and kala-azar, in the latter of which Rogers has described a special form of cirrhosis. The disease called '*infantile biliary cirrhosis of the liver*,' described by Ghose and Mackenzie as occurring in Calcutta and other parts of India in Hindu and Mohammedan children, appears to us to require reinvestigation, with a view to deciding whether it also is a variety of kala-azar. It is said to attack children under one year of age, and to be characterized by a low type of fever, associated with enlargement of the liver and spleen, jaundice, pale motions, dark urine, and sometimes vomiting of blood, œdema, and ascites, and ends fatally in three to eight months.

Acute yellow atrophy of the liver is not [illegible] ommon in Ceylon as in Europe, for, on an average, we have met with one or two cases per annum. It occurs in Ceylon more commonly in men than in women, but the cause appears to be quite obscure.

An extraordinary case of acute severe hepatitis and gastritis, which caused a considerable hæmorrhage to take place, filling all the small biliary ducts, the gall-bladder, the common bile-duct, the duodenum, jejunum, and ileum with blood, has been recorded by one of us in Ceylon. The inflammation occurred in a stomach which was altered by chronic atrophic gastritis. The hæmorrhage was caused by the blood passing from the damaged hepatic capillaries into the minute bile channels, and was due to the destruction of the walls of these capillaries and the liver cells. No definite cause could be found for this condition, which is decidedly rare.

Congestion and inflammation of the liver, together with abscess, are common in the tropics, and require special consideration (p. 1910).

Atrophic cirrhosis of the liver is very common in the tropics, and though generally there is a history of alcohol, still, this is by no means always so, and sometimes the cause is not evident. We believe that cirrhosis of the liver of malarial origin is much less frequent than is admitted by many authors. It will be shown presently that various parasites cause cirrhosis.

Primary cancer of the liver has been met with, but is very rare. On the other hand, secondary cancer is by no means rare. The only ***non-malignant growth*** which we have met with was an angioma.

The protozoal parasites which occur in the liver are ***Loeschia histolytica***, the cause of liver abscess; ***Leishmania donovani*** and ***L. infantum***, the causes of kala-azar and the infantile kala-azar; and the malarial parasites, as has already been noted. Coccidiosis has been found in the tropics in man several times.

With regard to the *trematode parasites* of the liver, *Fasciola hepatica* is only an occasional parasite of man. *Fasciolopsis buski* (*rathouisi*) has been seen in a Chinese who showed obscure liver symptoms, and no doubt microscopical examination of the faeces would make diagnosis possible but there is only one certain case, and the information regarding the symptoms is meagre. *Opisthorchis felineus* and *Amphimerus noverca* are the cause of opisthorchiosis, which will be considered late[illegible]s will clonorchiosis, caused by *Clonorchis sinensis*. *Dicrocoelium lanceatum* is considered to be too small to cause any serious symptoms while living in the bile-ducts. *Schistosoma mansoni* and *S. japonicum* may both affect the liver (pp. 1589 180[illegible]

With regard to *tape-worms*, *Tænia [illegible]inococcus* is not common, but we have met with one case of echinococcus in Ceylon, which was brought by a Boer prisoner [illegible] and Begbie has recorded another, not in the liver, but associated with the lung, in an old resident in Ceylon. One of us has recorded an invasion of the liver by Ascarides, and the formation of abscesses by the agency of these worms. We have [illegible] *Poro[illegible]halus armillatus* in the liver.

Disease of the [illegible]bladder is common in [illegible] tropics, and we have met with acute [illegible] chronic inflammation. Gall-stones are often met with [illegible]ably as sequelæ to typhoid [illegible] fever, but also arising from other causes. Suppuration of the [illegible]ile-ducts w[illegible] have only seen once, and œdema of the wall of the [illegible] bladder we have also only found once. *Obstructive* and *catarrhal jaundice* are met with fairly frequently in the tropics.

Rupture of the liver may take place as the result of traumatisms, and recently Herzog has recorded this accident in a Filipino woman as the result of a native obstetrical practice, which consists of traction on a cloth wound round the abdomen. In this case the rupture had been caused by the perforation of the tip of the eleventh rib into the fatty liver.

The pancreas, in our experience, is not infrequently found diseased. We have met with the following types of inflammation in Ceylon:—

1. Acute hæmorrhagic pancreatitis.
2. Acute suppurative catarrh of the ducts.

3. Subacute pancreatitis.
4. Chronic pancreatitis.
    (1) Syphilitic in the fœtus.
    (2) In the adult.
        (*a*) Chronic interlobular pancreatitis.
        (*b*) Chronic interacinar pancreatitis.
        (*c*) Chronic interlobular and interacinar pancreatitis combined.

It should be remembered that the subtertian parasite is one of the causes of *hæmorrhagic* pancreatitis. In addition we have seen cancer of the pancreas producing a blocking of the duct of Wirsung, and leading to a ranula which contained many pancreatic calculi. We have once seen an ascaris in the duct of Wirsung associated with a hyperæmic condition of the gland.

After this brief general statement, we must consider congestion of the liver, abscess of the liver, opisthorchiosis, and clonorchiosis.

TROPICAL LIVER.

Synonyms.- Congestion of the liver, Hyperæmia of the liver, Indian liver.

Definition.- Congestion of the liver is a hyperæmia brought about by many conditions, especially gastro-intestinal disorders.

Remarks. There can be no doubt that the European is apt to eat and drink more than is good for him on his first arrival in the tropics, and that this is bound to lead to an increase of blood in the liver, which physiological condition may easily become a congestion, with later blood stasis and diminution of the functional activity of the organ.

Climatology.- Congestion of the liver is a cosmopolitan complaint, but is much more commonly met with in the tropics than in the Temperate Zone.

Ætiology.- -Congestion of the liver is brought about by indiscretion in diet, such as too much, too rich, or too highly spiced foods, by alcoholic excess, and by chills.

Pathology.- Post mortem the liver is found to be swollen, dark red in colour, and drips with blood when cut into. The cells are often laden with fat, and, in addition to the changes in the liver, there will be added the pathological changes which have caused the congestion, and which are generally to be found in the alimentary canal, as well as those which have caused the death of the patient.

Symptomatology.- The illness begins with frontal headache, malaise and loss of appetite, with nausea or sickness, and a bitter taste in the mouth on awakening in the morning. The tongue is coated, and there are the usual signs of dyspepsia, associated with constipation and the passage of pale-coloured motions. The liver is enlarged and tender, and usually there is a sense of weight in the right hypochondrium, and pain below the right scapula or in the right shoulder, and there may be slight signs of jaundice in the yellow conjunctiva and sallow skin. The urine may be diminished in quantity, high-coloured, and with high specific gravity, and loaded with uric acid and urates. The nervous system is also affected, and the patient is usually very cross and irritable. The temperature is generally normal, but sometimes it rises, and when above 100° F. it is usual to call the disease hepatitis; instead of congestion of the liver. The common non-febrile variety lasts from two to seven days, but is liable to recur.

Varieties.- Congestion of the liver may be acute when associated with some other disease, or chronic when due to gastro-intestinal disturbance.

Diagnosis.--The diagnosis is based on the painful enlargement of the liver, which, in the absence of other disease, is usually unaccompanied with marked rise of temperature.

Treatment.- In the acute attack it is as well to keep the patient in bed and begin the treatment with a dose of calomel (gr. ii. to gr. v.), followed a few hours later by a saline in the form of magnesium and sodium sulphates or Carlsbad salts An effervescing mixture of ammonium carbonate (gr. ix. to gr. x.) and sodium bicarbonate (gr. xx.), with citric acid (gr. xv.), may be given every three hours, or a mixture containing ammonium chloride in some combination. At the same time hot fomentations or a thick coat of antiphlogistin may be applied to the region of the liver. The diet should consist of soups and milk, diluted with Vichy or barley water, and no alcohol in any form allowed.

When the condition has become chronic, the patient must be carefully dieted and placed upon a course of treatment with the above effervescing mixture and Vichy (Grande Grille), and when leave in Europe is available, should be sent to Vichy, Carlsbad, Harrogate, or Montecatini. He should avoid alcoholic stimulants and rich food of every description, and especially tinned food, and should restrict his diet to fowls, clear soups, fish, and well-cooked vegetables and milk, avoiding meat and curries.

Whenever the acute attack is over, the patient should be advised to take exercise daily -walking, riding, golf, or tennis, combined with the usual so-called liver exercises.

Prophylaxis.- Plain, simple, not highly spiced food should be taken, and such pernicious drinks as the heavy forms of beer, sherry, champagne, etc., should be avoided. If any form of alcohol is to be taken in the tropics, this should be Scotch whisky, well diluted, or light clarets, and then only in moderation. Chills must be avoided as carefully as possible, especially when there is a land wind, in the rains, and when changing from a warm to a cooler climate.

With regard to the cold bath, there is no doubt that the majority of people are unable to stand this in the tropics, and therefore it is better to use water with the chill removed.

Some persons are, however, distinctly benefited by a cold bath, and therefore individual peculiarities must be considered.

The most dangerous time for chills is in the night; therefore it is as well to sleep with some light blanket placed over the abdomen, and in flannel night attire. In the daytime a woollen undervest or cholera-belt may be worn. The clothes must be carefully changed whenever they become damp.

AMŒBIC ABSCESS OF THE LIVER.

Synonyms.—Hepatic abscess. *French:* Abscès du Foie. *Italian:* Epatite Suppurativa. *German:* Tropischer Leberabszess.

Definition.—Amœbic abscess of the liver is a suppurative hepatitis, caused by *Loeschia histolytica*—usually preceded by an attack of amœbic dysentery.

History.—Liver abscess was known to the ancients, and was operated upon as far back as the days of Hippocrates, while Galen recognized its connection with dysentery, and Morgagni studied its morbid anatomy. During the nineteenth century the disease was carefully studied by French surgeons, beginning with those of the army of occupation in Egypt, and also by the French colonial doctors and the Indian army surgeons. The discovery of *Amœbæ* or *Loeschiæ* emphasized the connection between liver abscess and dysentery. Kruse and Pasquale were the first to regularly find amœbæ in the liver abscess, and to state that, apart from the amœbæ, the pus was sterile. Later researches have confirmed this discovery, and have demonstrated that the pus of a liver abscess does not contain bacteria in most cases—a fact which agrees with our experience—and that the true cause of the malady is *Loeschia histolytica*.

Climatology.—Liver abscess is essentially a disease of the tropics and subtropical regions. It is very common in India and Indo-China, rather less so in Ceylon, Malaya, Java, Sumatra, and rare in Southern China. In Africa it is common in Egypt and North and West Africa (Gold Coast). In America it appears to be less commonly met with, being rare in the United States, West Indies, and British Guiana. It is also found, though rarely, in the Temperate Zone, in Spain, Italy, France, and even in such a northern country as England. There is no seasonal variation.

Ætiology.—The cause of the suppuration is *Loeschia histolytica*, and perhaps other varieties of *Loeschiæ*. It is more common in Europeans than in natives, and more so in males than females, and is usually a disease of adults. The most important predisposing cause is perhaps alcohol.

In monkeys one of us has recorded the occurrence of liver abscess due to an amœba (*Loeschia nuttalli* Castellani, 1907).

Pathology.—The *Loeschiæ* pass from the bowel via the portal vein into the liver, where they produce coagulative necrosis of the liver cells, which become formless and break up into granular débris. This necrosis is thought to be brought about by means of toxins produced by the *Loeschiæ*. The necrosed area undergoes liquefaction and forms the abscess, the contents of which consist of débris, endothelial cells, mononuclear leucocytes (rarely polymorphonuclears), red corpuscles, hæmatoidin, cholesterin, and rarely Charcot-Leyden crystals. The pus is usually sterile, and as a rule does not contain amœbæ, which are in the marginal wall of the abscess, and may extend into the liver tissue for some distance from the focal lesion. After the abscess has been opened, amœbæ may be found in the pus. The process of repair has not been fully worked out, but it appears as though the granulation tissue formed new connective tissue, in which new bloodvessels and proliferating bile-ducts may be seen, indicating the processes which may lead to repair.

Usually there is only one abscess, but it is not uncommon to find two, and there may be more. The abscess is generally found in the posterior part of the upper portion of the right lobe. It is rounded in form, with walls composed of degenerated liver cells and granulation tissue. Its contents may be thick, creamy pus, but more usually it is yellowish or brown coloured. On microscopical examination it consists largely of detritus, with a few degenerated liver and pus cells. The bacteria found in the pus, when it is not sterile, are streptococci, staphylococci, *B. coli communis*, and *B. pyocyaneus*, and occasionally some anaerobic germs. The abscess varies much in size, from a small hollow containing only 1 or 2 ounces up to a huge cavity with a couple of pints or more of pus, while even larger have been described. The size of the liver, apart from the abscess, also varies, being sometimes increased and sometimes diminished. Apart from the liver abscess, there are usually signs of old or recent dysentery in the colon, though these may be absent. There may be abscesses in other parts of the body, the spleen, the brain, etc., but these are rare.

FIG. 775.—AMŒBIC ABSCESS OF THE LIVER.

Symptomatology.—There is usually a history of a previous attack of dysentery, but this may be wanting. The disease begins insidiously with signs of congestion of the liver and fever. This fever is important, being irregular, sometimes remittent, sometimes intermittent, sometimes with long apyrexial intervals.

The X rays may show that the movement of the diaphragm is diminished on the right side, and attention has also been called to the arched 'cupola-like' curve of the upper aspect of the liver, as seen by radioscopy. The early stage, called by Rogers the 'presuppurative stage,' is of the utmost importance; for if it can be recognized and appropriate treatment applied, the disease may be stopped in a certain number of cases. If, however, this is not done, rigors may take place, and the fever usually becomes more severe, and a typical hectic temperature with night-sweats may ensue; while the patient complains of a dragging sensation on the right side, pain under the right shoulder-blade and in the right shoulder. This latter is a referred pain, due to the fact that the phrenic nerve arises from the fourth cervical nerve-root, the fibres of which supply the skin of the shoulder.

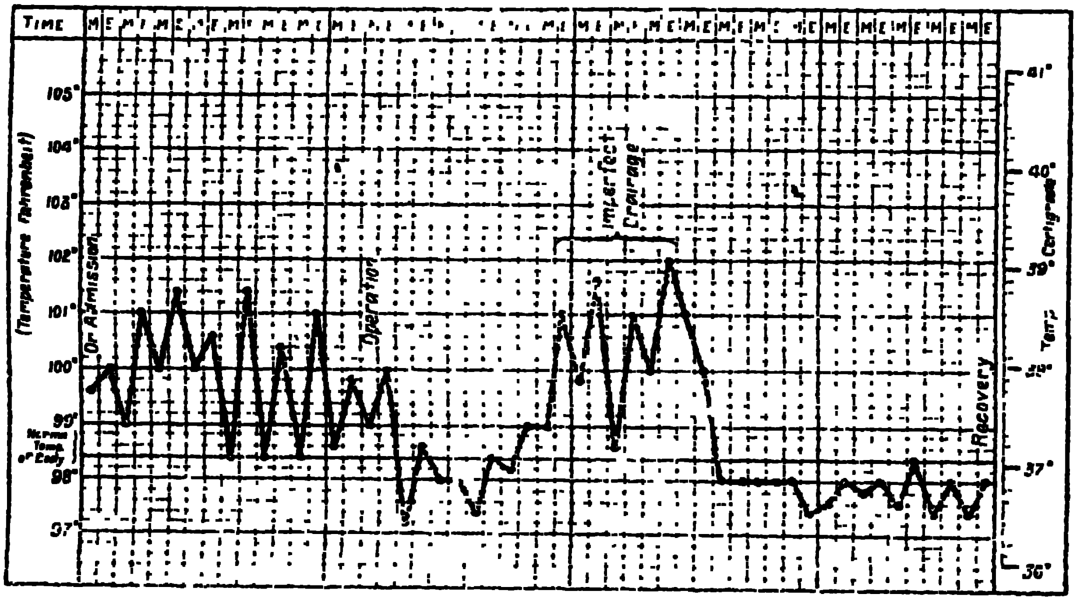

Fig. 776.—The Temperature Chart of a Case of Abscess of the Liver

A patient with an abscess of the liver often possesses a most typical facies. He lies on his back, with his legs drawn up; his face is drawn, and of a pale yellow colour, and the ocular conjunctiva possesses a peculiar bluey-whitish colour. It is said that sometimes the right pupil is dilated, but in our experience this is not a constant symptom. Generally he is emaciated, and deep inspiration is painful; hence the breathing is costal in character, and often there is a slight cough. The hands and feet are often cold and clammy to the touch.

On inspecting the abdomen and chest, the right hypochondrium will be noticed to be bulging, while the liver is enlarged and tender. On palpating the front of the abdomen, the right rectus muscle may be felt to become suddenly rigid—a most characteristic sign—while the left is not affected. On percussion the liver is found to be enlarged, and pain may be produced by pressure in the epigastrium or over an intercostal space. These painful spots are of importance in localizing the site of the abscess. On listening over the lower part of the chest, fine crepitations or friction sounds may be heard.

Usually liver abscess is accompanied by some anaemia and some increase in the number of the total leucocytes, but this appears to vary, being greater if the abscess is small and deeply seated, and less so if large and superficial. According to Rogers, the ratio of white to red corpuscles varies from 1 : 517 to 1 : 126. With regard to the differential count, the polymorphonuclear leucocytes are but slightly increased, but the lymphocytes are usually more than normal. Léger gives the differential count as being: Polymorphonuclears, 78·37 per cent.; lymphocytes, 17·44 per cent.; mononuclears, 3·15 per cent.; and eosinophiles, 0·70 per cent., which closely agrees with Rogers' figures, which are: Polymorphonuclears, 74 to 87 per cent.; lymphocytes, 7 to 22 per cent.; mononuclears, 3 to 7 per cent.; eosinophiles, 0 to 4 per cent. In some of our cases there was no polymorphonuclear leucocytosis, while on several occasions, even in non-malarial subjects, there was a relatively large mononuclear increase. The number of sudanophile leucocytes tested according to the Cesaris-Demel method is often increased.

The urine is usually diminished, and its excretion is said to be altered, so that the greatest quantity is passed between 12 midnight and 12 noon, being especially increased in the early morning.

If the abscess is allowed to continue its own course, it may burst into the lung, causing signs of pleurisy and pneumonia, associated with the expectoration of characteristic brown or reddish-brown gummy, viscid, purulent matter; or into the stomach, when a similar material will be vomited; or into the bowel, when it will be passed *per anum*. It may also burst into the pericardium or the peritoneum, or into the vena cava, all of which cases are bound to end fatally. If it does not burst, the patient may die of exhaustion.

The duration of a liver abscess is very variable, being from a few weeks to several months, and even years.

Diagnosis.—The diagnostic points in abscess of the liver are: A history of dysentery; fever, generally of a serotine type, with sweatings, not yielding to quinine; painful enlargement of the liver; the characteristic pain in the shoulder; the rigidity of the right rectus; the loss of movement in the right side of the diaphragm, and the frequent cupola-shape of the liver on radioscopy; and, above all, the discovery of the pus by exploratory puncture, as described below.

The differential diagnosis between the presuppurative and the suppurative stages is often impossible without a puncture, but sweating, high intermittent temperature, if present and not influenced by the emetine treatment, is suspicious that suppurative changes have begun.

Pleurisy with effusion on the right side can be distinguished from liver abscess by the presence of Grocco's paravertebral triangle on the left side. Moreover, in pleuritic effusions the upper limit of the dulness is horizontal, while in liver abscess it is convex.

Another diagnostic point to which Manson has drawn attention is that the enlarged liver gravitates with changes of position much more distinctly than pleural effusions. If the dulness in the mid-axillary line diminishes notably when the patient lies on his left side, the case is probably one of liver abscess. It is to be noted, however, that a right pleural effusion and a liver abscess may coexist. Pneumonia on the right side with congestion of the liver may also lead to difficulties, which must be met by careful physical examination and the microscopical and bacteriological examination of the sputum. Malarial fever can be diagnosed from the fever of hepatitis by examination of the blood and the presence of the enlarged spleen. In those cases of liver abscess in which fever is the only symptom the diagnosis may be extremely difficult, and may require all modern bacteriological methods to exclude Malta fever, malaria, septicæmia, and typhoid, etc. When in doubt, an exploratory puncture should always be made, for it can do no harm, and may relieve the congestion. When a long needle is introduced into a liver abscess, it moves regularly with respiration. Purulent cholecystitis in most cases gives no trouble on diagnosis, as the enlarged gall-bladder can be easily felt, and there is generally a history of hepatic colic.

Syphilitic gumma of the liver may show many symptoms in common with liver abscess, including the intermittent fever, as we have twice noted. The positive Wasserman reaction and the action of potassium iodide in full doses clears the diagnosis.

Cases of leukæmia, pseudo leukæmia, tropical splenomegaly, and kala-azar have been mistaken for liver abscess, but in all these conditions the spleen is also greatly enlarged.

In this connection we may emphasize the necessity for the examination of the blood in order to exclude leukæmia, otherwise a fatal hæmorrhage may follow such a simple operation as puncture of the liver. Liver abscess is usually easily diagnosed from hydatid disease, but when purulent changes have taken place in the latter the diagnosis may be impossible, except by the history and the eosinophilia.

Prognosis.—If the abscess is left unoperated for a long time, the prognosis is very bad, as the danger of exhaustion and septic infection is great. If the abscess has burst into the lung, the prognosis is also bad, but better than if it had burst into the bowel. Since operative measures have come into more common use the mortality has decreased, according to Dujardin Beaumetz, from 82 per cent. to 32 per cent. The operation wound may occasionally become phagedænic.

Treatment.—If a case is suspected by the symptoms and blood-counts to be in the 'presuppurative stage,' emetine or ipecacuanha should be administered, and should be given with the precautions already mentioned under Amœbic Dysentery, and the latter must be continued for several weeks after every sign of hepatitis has disappeared.

It, however, an abscess is believed to have formed, there should be no delay in making an exploratory puncture.

For this purpose a needle 3½ inches in length, but preferably not longer, because of the danger of injuring the vena cava, should be rendered sterile by boiling in plain water, but must not be dipped into an antiseptic lotion nor into spirit. This needle should be capable of being fitted on to a glass syringe or an aspirator.

The patient should be placed under chloroform, and all arrangements should be made so that an operation can be performed at once if necessary.

The needle should be driven into the liver in the region of any definite swelling or pain, or, failing these, through the eighth intercostal space in the anterior axillary line, about 1 or 1½ inches from the costal margin.

The direction of the needle should be inward, slightly upward and backward, because the usual site of an abscess is in the upper and back part of the right lobe.

Aspiration by the syringe or the aspirator may reveal pus, or may fail to do so, in which latter event the needle must be carefully and slowly withdrawn, and its contents ejected on to a clean white dish, to see if it is composed of the grumous material of liver abscess. The needle should now be driven into the liver in different places and directions until some six to twelve punctures have been made. There is no danger in this procedure if performed with reasonable care, and it may even benefit the patient by performing what has been termed 'hepatic phlebotomy.' When the abscess has been located, the needle should be left *in situ* as a guide, and one of two procedures may be carried out: A. Aspiration; B. Operation.

The operation should, however, always be performed if the abscess has already burst into the lungs, the peritoneal or pleural cavities.

A. Aspiration.—This is preferable if the abscess is small, and consists of evacuating its contents, and the injection of a solution of 1 grain of emetine hydrobromide in 2 ounces of water, or the repeated irrigation of the cavity with a solution of bi-hydrochloride of quinine (3 to 5 grains to the ounce) by means of Rogers' flexible sheathed aspiration cannula.

B. Operation.—An operation is necessary if the abscess is large, if the pus is not sterile, if the abscess has burst into the lungs or a serous cavity.

The site of the operation depends upon where the pus has been obtained. Two principal places may be mentioned: (1) through the thoracic wall; (2) through the abdominal wall below the ribs.

Giordano and others have recommended a laparotomy and the localization of the abscess by the hand prior to the actual operation for evacuation of the pus. This may be useful in certain cases when there are no signs indicating the position of the abscess.

1. *Operation through the Thoracic Wall.*—An incision should be made through the parietes, including the site of the puncture,

through which pus was obtained. After the skin has been well retracted, a piece of a rib may require to be removed, thus exposing the diaphragm below the pleura, which must be incised and stitched to the margins of the wound, and the wound well packed with gauze.

The liver is now exposed, and two methods of procedure are open to the operator either to push a pair of dilating forceps along the needle, which has been left *in situ*, and thus to open up the cavity and evacuate the pus, and then, after inserting a double drainage-tube, to wash out the cavity with the quinine solution mentioned above, close up the wound, fix the drainage-tube in position, and dress the wound aseptically, or to adopt Manson's special apparatus.

Manson, after the preliminary incision, thrusts a trocar and cannula into the abscess, and, after withdrawing the trocar, passes a drainage-tube stretched on a probe into the abscess cavity, and then, withdrawing first the trocar and then the probe, the drainage-tube is left in position in the liver abscess, and, being firmly gripped by liver tissue, prevents leakage of pus into the abdominal cavity.

2. *Operation through the Abdominal Wall.* The usual method is to cut down upon the swelling or on to the liver, and if adhesions are found, to evacuate and drain the abscess. If there are no adhesions, the liver is fixed to the peritoneum by a few stitches of thick catgut or kangaroo tendon, but preferably not silk, and the wound is lined by iodoform gauze and left for two days, when, adhesions having formed, the abscess can safely be evacuated as described above. Manson's apparatus can, of course, be used in this position as well as through the thoracic wall.

Post-Operative Treatment. The dangers of the operation itself are but slight. The pleura may be opened, and if this happens, it should be carefully closed by stitches.

The post-operative complications are many, and include hæmorrhage, pneumothorax, pyothorax, pyopneumothorax, gangrene of the lung, and delayed chloroform poisoning, while a second abscess is not uncommonly met with, and must be relieved.

After the operation the temperature should fall to normal, and if this does not happen, a second abscess or one of the above complications may be suspected, unless, indeed, it is due to imperfect drainage, which must at once be rectified.

The dressings should at first be frequently changed, usually twice a day, and the cavity irrigated with quinine lotion. Good drainage is the essential of the post-operative treatment, and care must be taken that the drainage-tube is not too rapidly shortened, otherwise the temperature is apt to rise.

On recovery, the patient should, if possible, be given a holiday in the Temperate Zone. A short course of emetine or ipecacuanha after the operation wound has quite healed is distinctly indicated in order to prevent the formation of another abscess.

OPISTHORCHIOSIS.

Definition.—Opisthorchiosis is an invasion of the bile-ducts with *Amphimerus noverca* Braun, 1903 (p. 577), and *O. felineus* Rivolta, 1885 (p. 576).

Remarks.—*A. noverca* is said to be common in dogs in India, but has only once been found in the dilated bile-ducts of an Indian in Calcutta, who died with dysenteric symptoms.

O. felineus has been found in the dilated bile-ducts, and incidentally also in the intestine of human beings, cats and dogs in Tomsk. It caused a form of hepatic cirrhosis.

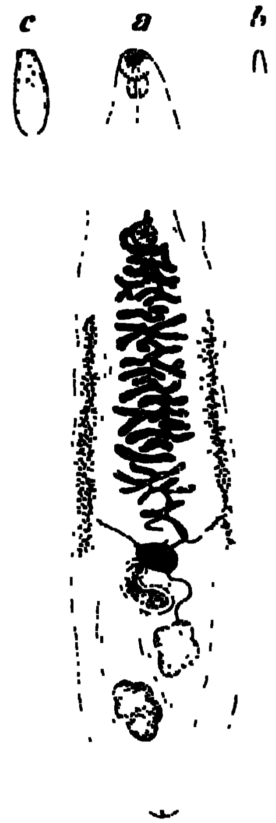

FIG. 777. *Opisthorchis felineus* RIVOLTA.

(After Looss.)

CLONORCHIOSIS.

Definition.—Clonorchiosis is the invasion of the bile-ducts with *Clonorchis sinensis* Cobbold.

Climatology. This parasite occurs in China, Indo-China, and Japan.

Pathology. These parasites occur in dogs and cats, but the method of infection is quite unknown. In man they live in the bile-ducts, in the recesses in the wall of the dilated gall-bladder or of the bile ducts, and in the duodenum. They may also be found in abscesses apparently unconnected with the liver. The ova are found in the alimentary canal and the fæces. The liver becomes enlarged, and may be darker in colour, while it is atrophied in the neighbourhood of the dilated ducts. The intestine may show catarrhal inflammation. Often the spleen is also enlarged, and there may be ascites or œdema. Ova have been met with in the abdominal lymphatics, while the flukes themselves have been found in a lumbar abscess. The blood shows an eosinophilia.

Symptomatology.—There is an abnormal appetite, but the general health remains good for some time, though the liver enlarges and becomes painful, while jaundice may be present. The spleen also enlarges. The disease is apparently very chronic, but towards the end emaciation, ascites, œdema about the feet and legs, and diarrhœa lead to death from exhaustion. Abscesses may form.

Diagnosis.—The presence of the worms can only be diagnosed by finding the eggs in the fæces (see p. 578).

Prognosis.—The prognosis is bad, as no cure is known.

Treatment.—An attempt may be made to kill the worms by thymol or *Filix mas*; otherwise the treatment must be symptomatic.

Prophylaxis.—Nothing can be said as to prophylactic measures until the method of infection is known.

CHAPTER LXXXIV

DISEASES OF DUCTLESS GLANDS AND METABOLISM

General remarks—The thyroid system—The suprarenal system—The thymus system—Other ductless glands—Diabetes—Macies perniciosa—References.

GENERAL REMARKS.

Of late years much work has been performed with regard to the ductless glands, their functions, and their part in the production of disease. In the tropics McCarrison has been the pioneer with regard to the thyroid gland; and it is hoped that as years pass the other systems will be equally well studied. We are only able to give these important subjects a passing reference, but they deserve much fuller attention, and for this purpose we offer the reader references at the end of this chapter.

THE THYROID SYSTEM.

The thyroid system consists of the thyroid gland and the parathyroids, with probably the addition of the pars intermedia of the pituitary gland. The action of these organs has been the object of much study in Europe and America, as can be noted by a reference to Biedl's writings, while McCarrison in the tropics has opened up the way to the solution of many diseases in an excellent manner.

The various pathological phenomena associated with this system may be divided into two classes—viz., those associated with *hypothyroidism* or insufficiency of functional activity, and those connected with *hyperthyroidism*, or excess of functional activity, and each of these, again, may be applied to the thyroid gland or to the parathyroids.

Thus insufficient activity upon the part of the gland itself may produce benign chronic hypothyroidism of Hertoghe, myxœdema, and cretinism, while exalted activity is believed to be responsible for goitre, Graves' disease, and psychic exaltation. The parathyroid glands when working insufficiently may cause tetany, myoclonia, myotonia, myotonia periodica, and paralysis agitans, but when in a condition of hyper- or dysactivity may be responsible for myasthenia or myotonia periodica.

With regard to the factors which produce these changes in the thyroid system McCarrison points out that they are three in number —viz.:—

A. *Nutritional.*—Defective and improper foods.

B. *Infective.*—Insanitary surroundings, bacterial and other toxins, infectious disease, constipation, intestinal stasis, and their associated toxæmias.

C. *Psychical.*—Fright, grief, worry, consanguinity in marriage, and heredity.

He shows that these factors can produce more or less hyperplasia in the gland, followed by fibrosis and atrophy, and that during this there is an alteration in the quantity and quality of the secretion passed into the blood.

He divides the hyperplasias into two groups. In the first he places those of *endemic areas due to a specific infecting agency*, such as endemic goitre, slight hypothyroidism, and he shows that these conditions in the parent may become congenital goitre, hypothyroidism, endemic cretinism, cretinous idiocy, with deaf-mutism and tetany in the descendants.

In his second group he places such hyperplasias as are due to toxæmia or thyroiditis, and as such he mentions simple toxæmia, goitre, and slight hypothyroidism as one section, myxœdema as a second section, and Graves' disease as a third section; and these occurring in parents may produce much the same results in the descendants as in the first class, but in this condition it will be sporadic and not endemic cretinism.

Diseases of the thyroid gland are quite common in parts of the tropics with which we are acquainted. Myxœdema has been seen by us in Ceylon, but is rarer in the tropics than in the Temperate Zone; goitres, parenchymatous and adenomatous, have been met with by ourselves in Ceylon and in Africa, and by Singer in Abyssinia. Exophthalmic goitre has been especially noted as far from rare by Singer in Abyssinia and Émile in East and Central Africa, but is very rare in India and Ceylon.

ENDEMIC GOITRE.

Synonym.—Endemic thyromegaly.

Goitre is much more prevalent in the tropics than has been realized hitherto, and we have met with it frequently in Ceylon and Africa.

Climatology.—It is a cosmopolitan disease which though frequently met with in hilly districts, is also, in our experience, quite common in low-lying lands. It does not appear to be associated with any geographical or geological condition.

Ætiology.—The general tendency of the present time is to consider that goitre is a parasitic disease, and this view has been strengthened by the recent important experiments of McCarrison on men and Bircher on rats, which, together with the previous ones of Lustig, Grassi, and many others, tend to show that the causal agent lives in earth and passes via potable water to man, in whose alimentary canal it passes a parasitic existence. The nature of this *contagium vivum* is unknown, but McCarrison is inclined to suspect an amœba. Chagas has shown that goitre is a part of the syndrome in chronic American trypanosomiasis.

Symptomatology.—A new-comer to an endemic district may notice after a few weeks' residence that the neck has begun to swell, and on examination this is found to be due to an incipient goitre. On removal from the district, or after almost any method of treatment, the swelling will decrease. If, however, the person continues to reside in the endemic region, the swelling will either continue or return, and this will continue to occur until a more or less permanent hypertrophy results. Usually the swelling affects the whole gland uniformly, but often one lobe may be more hypertrophied than the other. As time goes on the gland becomes permanently enlarged, and may undergo cystic or adenomatous changes.

FIG. 778.—GOITRE IN A SINHALESE WOMAN.

Treatment.—The treatment consists in removal from the endemic area, and in a course of intestinal antiseptics e.g., salol and thymol, 10 grains night and morning. McCarrison recommends a polyvalent vaccine made from the bacilli found in the fæces of persons suffering from the disease. Iodine therapy is strongly recommended. The syrup of the iodide of iron in 5-minim doses combined with 5 grains of iodide of potash is advised as an initial dose, and this may be gradually increased to three or four times this quantity. The liquor thyroidei of the British Pharmacopœia is excellent, or fresh tabloids in doses of 2-5 grains combined with 10 grains of bicarbonate of soda and taken at night. The sour-milk treatment has also been recommended.

Prophylaxis.—The most important prophylactic measure is to filter and boil the drinking-water when compelled to visit or live in an endemic region. The patient must also lead a life free from emotion, if possible.

Congenital Goitre.

McCarrison has pointed out that this is extremely common in certain Himalayan villages. Nearly every man and woman in these situations is goitrous, and congenital goitre may be present in 60 per cent. of the infants at the breast. The mothers of these children are often myxœdematous. The condition rarely calls for treatment, as the victims usually die at or shortly after birth or recover spontaneously, but the mother and child may be given the British Pharmacopœia liquor thyroidei, of which 1 to 2 minims may be given to the child at night.

Endemic Cretinism.

According to McCarrison, the cretinism of the Himalayas, which does not show itself until about six months after birth, may be divided into:—

1. *The myxœdematous type.*
2. *The nervous type.*

Myxœdematous Type.—There is failure in growth, dwarfism, skeletal deformities, persistent infantile condition of the sexual organs, and a lack of intellect, and deafness or deaf-mutism, as well as impairment of the sensory and muscular systems.

Nervous Type.—This is a state of cretinous idiocy associated with cerebral diplegia and tetany.

The treatment of these conditions is the fresh liquor thyroidei (B.P.) in doses of 1-2 minims at bedtime, combined with grey powder and bicarbonate of soda during the first fortnight. The dose of the liquor is gradually increased until 5-10 minims are given in a day. If the liquor is not available, the dried gland in powder may be given in ¼-½ grain doses, working up to 5-7 grains per diem.

Endemic Tetany.

This is found in goitrous districts in the Himalayas, where it is called 'hatti fallategen,' or turning of the hands. It is characterized by bilateral, intermittent, and usually painful spasms of the hands and feet, and at times other parts of the body, and increased excitability of the nervous system.

During the attack calcium salts should be administered.

The curative treatment is to combat the intestinal toxæmia by calomel and intestinal antiseptics, followed by thyroid therapy as indicated above. Rickets must also be treated. The diet should consist of milk, *and meat should be avoided.*

THE SUPRARENAL SYSTEM.

In 1563 Bartholomeus Eustachius Sanctoseverinatus recognized the suprarenal capsules as distinct organs, but it was not until 1855 that Addison's researches aroused deep interest in these glands.

No case has been as yet recorded of the absence of these capsules *as well as* of the possible accessory suprarenals in man. *Acute suprarenal suppression* is caused at times in man by hæmorrhage, and we quote such a case below. The syndrome of these cases is fever, nervous symptoms, and signs of peritonitis followed by death. Malaria may cause these signs.

Chronic suprarenal suppression may be caused by malaria, and is characterized by the signs of Addison's disease viz., apathy, adynamia, gastro-intestinal and nervous disturbance, associated with bronzing of the skin and mucous membranes, and a chronic cachexia, with frequently attacks of diarrhœa or convulsions, and ending in coma and death.

In the tropics we have met with Addison's disease once in a European, and with hæmorrhage into both the suprarenal capsules twice—once in a still-birth after a breech presentation in a native child, and once in a case of acute suprarenal hæmorrhage in a European lady. This last showed symptoms so remarkable in character that a brief description may be given.

Acute Suprarenal Hæmorrhage.

After a year's residence in Ceylon, a young English lady, four months pregnant, was suddenly taken ill with fever associated with an abnormally quick pulse, great tenderness above the umbilicus, and pain in the small of the back on both sides. After a short intermission the fever returned, and rose to 104° F., with a pulse of 130, and quick respirations; the abdomen became much distended and very tender, and the bowels were constipated. All the organs were normal, as was the urine. Vomiting did not begin till near the end, when the tongue first became coated and then dry. Hiccough intervened before death on the thirteenth day. Treatment was without success in any way, and an exploratory laparotomy revealed no abnormality beyond bowels distended with gas. On post mortem examination, no pathological phenomena were seen, except hæmorrhages into both suprarenal capsules, and, judging by the histology, this may have been a case of localized malarial infection without any sign in the blood.

THE THYMUS SYSTEM.

The normal weight of the thymus at birth is 13·26 grammes, and it should increase till between eleven to fifteen years of age it should weigh 37-52 grammes according to Hammar, after which it decreases, until after sixty-six years it only weighs 6·0 grammes, and is then principally composed of adipose tissue. In 1858 Friedleben published the only monograph on this gland in health and disease. The gland is supposed in some unknown way to be associated with certain cases of sudden death (*mors thymia*), especially when there is the so-called *status thymicolymphaticus*, in which a much enlarged thymus is associated with hyperplasia in the lymph glands and lymphoid tissues all over the body.

Only once have we encountered a persistent thymus gland with some enlargement of the lymphatic glands, and this was in a case of sudden death.

OTHER DUCTLESS GLANDS.

We are not acquainted with observations referring to the other internal secretion [illegible] human diseases of the tropics.

DIABETES.

This disease is extremely common in the tropics, but more especially in Asia, and particularly in Ceylon, though we have met with it in Africa.

In India, according to Waters, it has been known since the days of the Susruta Samhita, where it is called 'madhumeha.' It was said to be unknown among the Chinese and Japanese, but Reid has collected 207 cases in China, and in Korea the complaint is called ' weet water disease.'

West says that it is rare in Hindu women, but that it does occur even in Hindu widows, and in general [illegible] may be said to be much more common in men than in women, and is most frequently met with in the better or educated classes.

The disease is the same as in the Temperate Zone, and will not be further considered here, except to point out the frequency of boils and carbuncles due to it, and also the occurrence of Kussmaul's coma, which may be induced by a malarial infection.

Pentosuria.

As in the Temperate Zone, so in the tropics, pentosuria may occur, but is rare, though it is necessary to bear in mind the possibility of its occurrence when the diagnosis of diabetes is made on the reduction of Fehling's solution. A simple method of diagnosis is by using Castellani and Taylor's mycological method of examination of the urine (see Chapter LXXXV., p. 1934).

MACIES PERNICIOSA.

Dr. Ernest Black gives the following account of this disease, which occurs among the aboriginal natives in the north of the State of Western Australia. It has also been reported among the tribes of the Northern Territory of the Commonwealth, where it is called 'living skeleton' disease.

Though the white settlers regard it as a form of consumption, it is not tubercular, and it does not appear to be associated with any malignant growth. It does not correspond clinically with any known tabetic disease. In one case seen in the earlier stages the pancreas was most affected. There is a progressive enlargement of the liver and spleen, the abdomen becoming considerably distended. All the fat disappears and the muscles atrophy, but retain the power of movement. The appearance is quite characteristic—extreme emaciation of the whole body, with a protruding abdomen. Ultimately, through increasing weakness, walking becomes impossible, a serious matter with these nomadic people, which may account for the fact that the few cases of long duration which were observed had remained near white settlements. The course of the disease is slow, but, so far as could be ascertained, it always terminates fatally. Only one case was seen in a child, who died within a year, whereas in the case of a woman who appeared to be middle-aged it was said to have already lasted over two years.

The cause of the disease is unknown. No parasite has been found in the blood of patients examined in the endemic areas.

Further investigation is necessary to see whether this disease is a type of tropical splenomegaly (*vide* p. 1303).

CHAPTER LXXXV

DISEASES OF THE URINARY ORGANS

General remarks—Bilharziosis—Urinary amœbiasis—Oxaluria—Urinary myiasis and canthariasis—Chyluria—Mycological urinary tests—Test for quinine in the urine—References

GENERAL REMARKS.

RENAL disease in all its forms is frequently met with in the tropics, where nephrolithiasis, pyonephrosis, and pyelitis, with all their associated phenomena, are by no means rare. Stone in the bladder is common in certain regions, as is prostatic hypertrophy. But the only disease which really concerns us in this work is urinary bilharziosis, caused by *Schistosoma hæmatobium*. Tumours of the bladder are not common in our experience. Prostatic abscess is met with at times. We have observed various mycoses of the genito-urinary organs due to fungi of the genera nocardia, aspergillus, monilia, cladosporium. Native children in some parts of Africa (Sudan) suffer very often from a complaint called by the Arabs 'har boul,' characterized by severe burning on passing urine. This condition is due to concentrated acid urine and the presence of gravel. Cystinuria is rare, but we have met with a case.

In the present war a form of nephritis has been noticed in soldiers in the trenches (trench nephritis).

BILHARZIOSIS.

Synonyms.—Urinary schistosomiasis, Endemic hæmaturia, Bilharzia disease.

Definition.—Bilharziosis is infection with *Schistosoma hæmatobium* Bilharz, 1852, the eggs of which irritate and invade the urinary tract, and cause hæmaturia and cystitis.

History.—The disease has been endemic in Egypt since ancient times, Ruffer having demonstrated calcified eggs of *S. hæmatobium* in mummies of the twentieth dynasty (about 1250-1000 B.C.). Hæmaturia was much noticed by the French army surgeons in 1799 to 1801; but it was not till 1851 that Bilharz made the discovery that the disease was due to *S. hæmatobium*.

Climatology.—Bilharziosis is prevalent in Africa, especially in Egypt and the Cape, but it is also met with in Asia, in India, Syria, and Mesopotamia, and in the West Indies. In Egypt, according to Sandwith, infection probably takes place in the early winter months when the floods have subsided.

Ætiology.—The cause of the disease is *Schistosoma hæmatobium.* The life-history is described in Chapter XXIV., p. 584. The method of infection is by the cercariæ penetrating the skin or mucous membranes and developing into adults, which live and copulate in the portal and vesical veins, while the eggs leave the body with the urine.

It occurs in any race and at any age, except infancy, but is more common in males than in females, due, it is thought, to the men washing in streams and working in the fields barefooted. According to Miss Elgood's investigations, the disease is common also in young girls, even in those who do not bathe, and who use filtered water. It is rare in Europeans, being much more common among the natives, in whom it is prevalent among the working classes, especially the field-labourers.

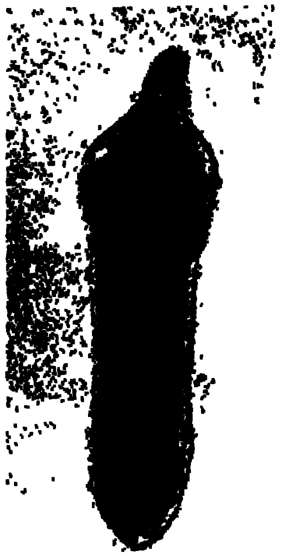

FIG. 778A.—MIRACIDIUM OF *Schistosoma Hæmatobium.* (× 300 DIAMETERS.) (Photomicrograph.)

FIG. IOTOGRAPHS OF *Bulinus contortus*.

Pathology. The worms live in the porta vein, but proceed to the venules of the bladder to lay the eggs. The irritation of these eggs excites a round-celled infiltration, sometimes of a very extensive nature, giving rise to a sort of bilharzial granulation tissue—that is, a tissue composed of round cells and eggs. Madden divides the pathological changes into two classes- the hypertrophic and the atrophic. In the former, which is more common in mucous membranes, there is proliferation of the epithelium, with the formation of flattened projections or papillomata, while vesicles may also form, and, according to Madden, by bursting, give rise to the ulcers which at times are seen.

The ova may escape from the mucosa, according to Looss, without the aid of ulceration, by working their way between the epithelial cells into the lumen of the viscus. Underneath the mucosæ the round-celled infiltration forms the typical bilharzial granulation tissue, and leads to much thickening of the wall of the viscus, and, proceeding to connective-tissue formation, may cause marked changes. Lesions may also be found from the pelvis of the kidney to the meatus urinarius, but are most common in the bladder.

Morbid Anatomy.—The earliest changes are found in the bladder in the formation of a general infiltration and thickening of the mucosa with bilharzial tissue. Over this thickened mucosa is a layer of adherent mucus, which is apparently protective. In this mucus numerous eggs are found. Later hyperæmic patches are found associated with vesicles, which are especially marked around the trigone, and contain a whitish fluid in which there are eggs. The hyperæmic patches increase in size and thickness, and the whole bladder becomes much thickened. Papillomata of all shapes and sizes are formed principally on the trigone and the posterior wall of the bladder. These papillomata bleed readily, giving rise to the hæmaturia.

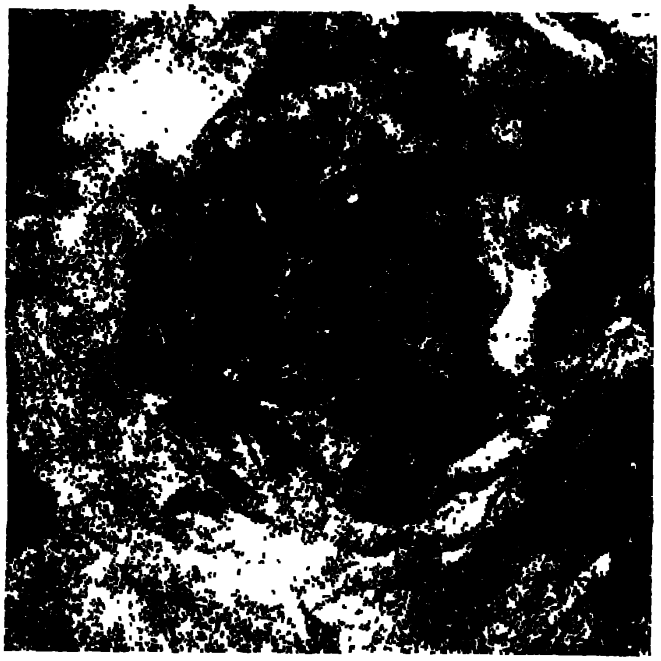

FIG. 778C.—BLADDER SHOWING LESIONS OF BILHARZIOSIS.

As the eggs increase in amount, connective tissue forms round them, and they die and become calcified, thus giving rise to brownish-yellow, sandy patches, not protected by mucus, and leading to an atrophy of the mucosa of the viscus.

The urine collects in the hollows between the papillomata, and, decomposing, gives rise to phosphates, which produce a whitish incrustation on the bladder wall. The orifices of the ureters may become obstructed, giving rise to backward pressure, causing hypertrophy of the ureters and hydronephrosis. Septic infection is very liable to spread from the bladder up the dilated ureters to the kidney. Bilharzial tissue may also form in the ureters and the pelvis of the kidney, and take the form of infiltrations and papillomata. Calculi may also form in the bladder, and interstitial nephritis in the kidney.

As the bladder becomes infiltrated it rises in the abdomen, and may be felt above the pubes, and in this situation infection may spread to the abdominal wall. In this case the typical bilharzial tissue forms in the subcutaneous tissue, and, working its way to the surface, forms a sinus lined with bilharzial granulations containing eggs and discharging pus. These sinuses may spread, and a large area of skin become involved.

Bilharzial tissue may also form in the prostate and urethra.

Symptomatology.—The incubation is not known, but, according to Sandwith, it varies from three to six months. At first no symptoms are exhibited, but in course of time frequency of micturition, with a sensation of burning in the perineum or along the urethra, may be noted, while there is some straining after passing urine. In due course hæmaturia appears, beginning with a few drops of blood either at the end of micturition or after the urine has been passed. Usually there are no symptoms with this hæmaturia, but there may be scalding. The urine is clear and acid, but some mucus may be passed, which, if centrifugalized or allowed to settle, shows the typical ova and, of course, red cells, leucocytes, and epithelial cells. Usually the general health is good, but pains in various directions may be felt—*e.g.*, in the back, the perineum, the gluteal region, or down the leg.

Sooner or later the urine begins to stagnate in the hollows in the mucosa formed by ulcers and by papillomata. When this happens, the urine becomes alkaline and turbid, containing pus and phosphates, as well as decomposing blood and ova. With this decomposition of the urine cystitis appears, and the sufferings of the patient begin in earnest, with at first increased, and later almost constant micturition, scalding pains in the perineum and the scrotum, together with tenesmus, which increase until he can rest neither day nor night. In order to add, if possible, to his miseries, the prostate may enlarge or a stone may form in the bladder, which may be composed of uric acid or oxalates covered with phosphates, or simply of phosphates. If the bladder is examined in this stage it will be found to be thickened, and may be felt above the pubes. Fistulæ may form in the abdominal wall above the pubes, or the urethra may be attacked. The urethral symptoms begin with localized pain and the formation of a lump which develops an abscess, and later urinary fistulæ.

The patient now becomes weak and anæmic, and begins to suffer from pyonephrosis. The enlarged kidneys, and at times even the ureters, may be felt through the abdominal wall. In course of time septicæmia sets in, and the patient dies. On the other hand, cases which have left the endemic area may slowly recover, the ova ceasing to be passed.

Complications.—Retention of urine from blocking of the urethral opening by papillomata or a stone may occur. Stone in the bladder as has already been mentioned, is an important factor in increasing the sufferings of the patient, but its symptoms may be masked by those of the disease. Urinary fistulæ has already been referred to, and cancer may also occur as a complication of the disease, but is said to be rare. Ankylostomiasis and pellagra and other diseases may also complicate a case.

Diagnosis.—The only certain diagnosis is by the discovery of the ova, but hæmaturia in the endemic area must always be regarded with suspicion. Centrifugalization is necessary when the ova are in small numbers.

Fairley recommends a complement fixation-test with an antigen prepared from livers of infected snails.

Prognosis.—The prognosis depends largely upon the possibilities of infection, and is therefore better if removal from the infected area is possible; for, according to Sandwith, most cases cease to pass eggs within three years of leaving that area.

FIG. 778D.—EGG OF *Schistosoma hæmatobium* IN URINE. (Photomicrograph.)

Treatment. McDonagh and Christopherson have recommended the intravenous injection of tartar emetic, which should be administered in the same way as for intestinal schistosomiasis (p. 1864). Various treatments, such as injections of sulphuretted hydrogen and carbon dioxide gases into the bladder, have been suggested. The drug commonly used in the past was liquid extract of male fern, in 5-minim doses, three times a day, continued for a long time. It is said to reduce the hæmaturia and lessen the discharge of eggs. Emetine has been recommended by several observers. Madden recommends the washing out of the bladder with injections of silver nitrate, beginning with 1 in 10,000, and increasing the strength gradually; or quinine in a 1 per cent. solution; or adrenalin in normal saline solution.

In addition, boracic acid, in 5-grain doses, three times a day, or helmitol, in 15 grain doses, three times a day, urotropine, salol, benzoic acid may be given, or the ordinary buchu and hyoscyamus mixture may be administered. Large quantities of water or Vichy water should be drunk to wash out the urinary passages.

If a calculus is present, it must be removed by lithotrity or by perineal, not suprapubic, cystotomy. Cock's operation of cystotomy and drainage of the bladder gives relief in the later stages, but Madden says that this only lasts for a few days, and then usually diarrhœa and septic infection set in, and the patient dies in about two weeks.

With regard to fistulæ, they ought to be thoroughly dissected out and this may mean a very prolonged operation if it is to do any good.

McDonagh, who first used antimony in bilharziosis in 1912, prefers colloidal antimony, which he gives intravenously and intramuscularly in doses of 0·5 c.c. to 2 c.c. of a 0·2 per cent. emulsion.

Salvarsan has been used by several observers, with doubtful results.

Prophylaxis.—As the method of infection is unknown, it can only be suggested that bathing in polluted or possibly polluted water is dangerous, and drinking-water must be carefully boiled and filtered. The urine of persons suffering from the disease should be mixed with some disinfectant before being disposed of.

URINARY AMŒBIASIS.

Definition.—Urinary amœbiasis is the infection of the urinary tract with amœbæ, which most commonly are *Loeschia histolytica* (Schaudinn, 1903).

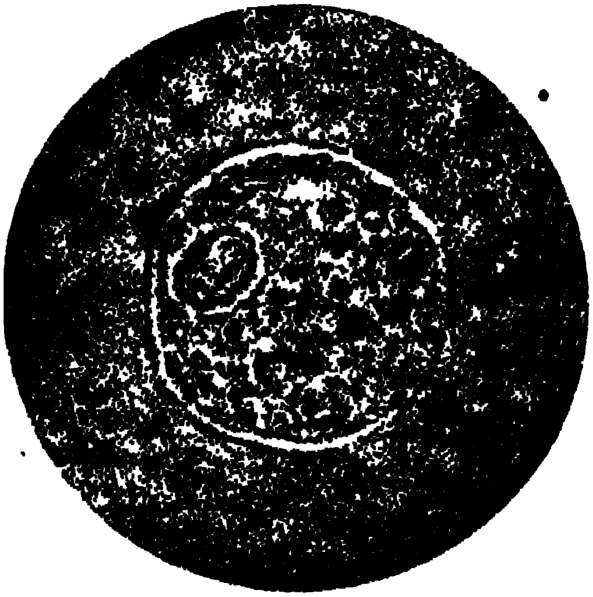

FIG. 779.—PRECYSTIC STAGE OF *Loeschia histolytica* (SCHAUDINN, 1903, *emandavit* WALKER, 1911), AS SEEN IN URINE IN A SUDAN CASE. FRESH AND UNSTAINED SPECIMEN. (× 1,500 DIAMETERS.)

(Microphotograph. This illustration may be examined with advantage by means of a reading lens.)

Historical.—In considering the history of urinary amœbiasis, it is convenient to divide the subject into infections low down in the urinary tract, into those which are situate high up, and into those of which the site is unknown.

Low Down in the Urinary Tract.—Amœbæ were first described in urine and in vaginal secretion by Baelz in 1883, when he named the particular species which he saw *Amœba urogenitalis* Baelz, 1883. This amœba was provided with a synonym by R. Blanchard in 1885, when he called it *Amœba vaginalis* R. Blanchard, 1885. It measured some 23-50 microns in diameter, was actively motile, extruded short and blunt pseudopodia, possessed granular cytoplasm containing a vesicular nucleus and phagocyted red blood-corpuscles, while cystic stages of the same organism were also observed. There is, in our opinion, no reason to doubt that this is the same species as the organism variously known at the present time as *Loeschia histolytica* (Schaudinn, 1903, *emendavit* Walker, 1911); *Entamœba histolytica* Schaudinn, 1903; *Entamœba tetragena* Viereck, 1907; *Amœba dysenteriæ* Councilman and Lafleur, 1891; and *Amœba coli* Loesch, 1875; and by various other names.

The unpleasant point is that if the rules of zoological nomenclature are pressed we ought to call the amœba of dysentery by Loesch's name.

The following cases are known to us: —

(1) Baelz's patient was dying from pulmonary tuberculosis, and it was only shortly before death that hæmaturia associated with severe tenesmus of the bladder set in, and Baelz considered that the bladder as well as the vagina was infected, but it is not evident from abstracts of his paper that any post-mortem examination was made.

(2) In Jurgens's 1892 case the amœbæ were found by post-mortem examination to come from mucous cysts in the bladder of an old woman who had suffered from cystitis, and in whose vagina they were also found.

(3) In 1911 Craig found *Loeschia histolytica* Schaudinn, 1903, in an infection of the bladder in which the autopsy showed a minute fistula between the ulcerated intestine and the bladder.

(4) Lynn's 1914 Costa Rica case seems to have been probably caused by a vesical lesion, as the patient is reported to have felt 'a pain in the trigonum vesicæ at the end of micturition.' He responded very well to emetine treatment, as it is stated 'in the course of five days the vesicle tenesmus was relieved and the urine cleared'; moreover, there was no return of the symptoms after one month.

(5) and (6) Scott Macfie' second case was probably a bladder infection associated with bilharziosis, while his third and fully described case was probably an infection of the genito-urinary tract in the neighbourhood of the seminal vesicles.

High up in the Urinary Tract.—In these cases the site of infection is probably in the pelvis of the kidney.

(7) Posner's 1893 Berlin case began with a rigor and the passage of urine tinged with blood, which, when examined, showed red and white blood-corpuscles, hyaline and granular casts, and large granular bodies 50 by 28 microns, which slowly altered their shape, and which contained, among other things, red blood-corpuscles and one or more nuclei and some vacuoles. Posner, probably correctly, came to the conclusion that the pelvis of the kidney was affected, but seems to have considered that this infection began in the bladder.

(8) A similar case exhibiting signs of pyelitis without any vesical symptoms has been recorded by Chalmers and O'Farrell in the Anglo-Egyptian Sudan.

Site in the Urinary Tract Unknown.—(9) We have been unable to refer to the original papers written by Wijnhoff, by Jeffries, and by Fisher, and are therefore unable to state where the infection was situate.

(10) The very brief note by Ward, Coles, and Friel arouses the doubt as to whether the amœbæ really came from the patient, because they do not state whether these bodies were merely seen once or whether they were of frequent occurrence. They call the organism *Amœba urinæ granulata*, but, as Fantham has pointed out, in no case can this name stand.

(11) Scott Macfie, owing to the non-return of the patient to the hospital, was unable to define the site of the infection in his first case.

All the cases which we have met with have been associated with symptoms which have pointed to the pelvis of the kidney as the probable source of infection.

Climatology.—Cases are known in Europe, Africa, and Asia.

Ætiology.—It is possible that all reported cases were due to *Loeschia histolytica*.

Symptomatology—*Amœbic Pyelitis.*—With or without the history of previous amœbiasis in the form of amœbic dysentery or other amœbic infection, a person is seized with an attack of lumbar pain associated with the passage of turbid urine, with or without blood, and slight fever, the temperature rising to 99°-100° F.

The urine, if collected and examined after centrifuging, will be seen to contain a deposit of red blood cells, leucocytes, and amœbæ in a precystic stage, and more or less degenerate.

The blood, when examined, has been found to show:—

Polymorphonuclear leucocytes	61·0
Mononuclear leucocytes	8·4
Large lymphocytes	22·4
Small lymphocytes	5·6
Eosinophile leucocytes	2·2
Mast cells	0·4
Total	100·0

Amœbic Cystitis.—In these cases there is pain and straining at the end of micturition. On examination the urine shows motile amœbæ.

Treatment.—The treatment is to give urotropine by the mouth and emetine intramuscularly.

OXALURIA.

Definition.—Oxaluria is the deposit in abnormal quantity of oxalate crystals in the urine, and should be restricted to cases which show an increase in the quantity excreted in the day.

Historical.—The crystals of calcium oxalate were discovered by Donné in 1838, and were much discussed for a time, being made the basis of the oxalic acid diathesis of Prout, Golding, Bird, and Begbie; but as a result of Smoler and Bacon's investigations, this theory fell to the ground. In 1896 Dunlop attributed them to the oxalates in the food, and in 1900 Baldwin conducted a series of experiments upon dogs, and showed that fermentative intestinal disturbances associated with the absence of free hydrochloric acid in the gastric juice were the causal agent.

Climatology.—It may occur in any part of the world, but is very commonly met with in the tropics, in Europeans and natives alike. With regard to its presence in natives, Burkitt's observations in Chandira in Eastern Bengal are especially interesting.

Ætiology.—The normal quantity of calcium oxalate to be excreted in the urine is 0·5 gramme per diem. It may perhaps come from certain vegetal substances in the diet, but it is more likely that it is in some way associated with either proteid fermentation in the alimentary canal or proteid metabolism.

Miss Baldwin's experiments tend to show that if the carbohydrate food of a dog is abnormally increased hypochlorhydria may result, and with it oxaluria. Burkitt's observations support this, as he shows that the Manipuris (of Mongolian origin) living round Chandira in Eastern Bengal, and consuming nothing but vegetables and fruit, suffer excessively from oxaluria. Certainly treatment based upon the idea of too little acidity in the stomach is most successful.

Symptomatology.—Dyspepsia, pain in the lumbar region, shooting down the ureter, burning during micturition, and even hæmaturia, are signs of oxaluria. These symptoms may or may not be associated with signs of mild neurasthenia. If unchecked, oxaluria may lead to the formation of an oxalate calculus in the kidney or bladder, accompanied by the ordinary signs of stone in the kidney or bladder.

Treatment.—The treatment is simple and certain. A few minims of the dilute pharmacopœial preparation of nitrohydrochloric acid combined with ½ drachm of the compound tincture of cinchona bark and 1 ounce of the compound mixture of gentian, given three times a day before meals, is the best remedy.

URINARY MYIASIS AND CANTHARIASIS.

See Chapter LXVII., pp. 1628 and 1640.

CHYLURIA.

This is generally due to filariasis, and is described on p. 1608. Cases of schistosomic origin occur, and Remlinger has placed on record two cases due to hydatids, with hydatid membrane in the urine. Quarelli, in 1918, drew attention to a *malarial chyluria* associated with malarial parasites in the blood, and cured by quinine therapy, occurring in a person who had never left Italy.

URINARY TESTS.

Castellani and Taylor's Mycological Method for the Detection of Glucose, Lactose, Maltose, and Other Carbohydrates in the Urine.—The tropical practitioner generally bases the diagnosis of diabetes on the reduction of Fehling's solution by the suspected urine. Fehling, however, may be reduced by a number of other substances in addition to glucose—for instance, by lactose, galactose, maltose—and the detection of such substances by chemical procedures is long and requires much practice. Castellani and Taylor's mycological method will often be found simpler and easier. Castellani and Taylor thought that, just as various carbohydrates and other carbon compounds are used in the identification of certain bacteria and higher fungi, the reverse process might also be carried out—viz., bacteria and higher fungi might be used for the detection and identification of certain chemical substances. For many years ordinary baker's yeast (so-called German yeast) has been, of course, used to detect glucose, but this is the only sugar for which a purely mycological method has been used in pathological work, and, as a matter of fact, it is an unscientific method, as ordinary baker's yeast very often ferments galactose, maltose, saccharose, and other sugars, in addition to glucose. If a urine, therefore, is fermented by baker's yeast, this does not mean with certainty that it contains glucose, as stated in so many textbooks. Castellani and Taylor determine whether a substance is or is not a certain carbohydrate by testing on it whenever possible the action of two germs known to be identical in all their biochemical reactions, except on that particular carbohydrate. For instance, in order to see whether a certain chemical substance reducing Fehling is maltose or not, the substance is tested with two germs which are known to be identical in all their biochemical reactions, except on maltose, such as *Monilia krusei* Castellani and *Monilia pinoyi* Castellani. The procedure to detect, for instance, maltose in the urine is as follows. The urine is collected aseptically, or, if this is not feasible, is distributed in sterile tubes (each containing a small fermentation tube) as soon as passed, and then sterilized in Koch's stove for thirty minutes on two or three consecutive days. It should never be autoclaved, as autoclaving may alter the composition of the sugars and other carbohydrates present. Two tubes of the aseptic urine to which one-third or the same amount of sterile, sugar-free, peptone water has been added (to facilitate an abundant development of the organisms) are inoculated—tube No. 1 with *Monilia krusei* and tube No. 2 with *Monilia pinoyi*. The two tubes are incubated at 35° C. for twenty-four to forty-eight hours, and then examined. If No. 1 does not contain gas, while No. 2 contains gas, the urine, according to all probability, contains maltose.

To understand and properly carry out the method one must have, of course, an exact knowledge of the biochemical reactions of a certain number of bacteria and higher fungi which can be found at pp. [illegible] and 1082. The working and results of the method are seen at a glance in the following mycological formulas:—

URINE FEHLING-REDUCING.

1.	*Monilia balcanica* Castellani .. .	Gas	= glucose.
2.	*Monilia balcanica* Castellani .. .	O	= levulose.
	Monilia krusei Castellani	Gas	
3.	*Monilia krusei* Castellani	O	= maltose.
	Monilia pinoyi Castellani	Gas	
4.	*Monilia pinoyi* Castellani	O	= galactose.
	Monilia metalondinensis Castellani ..	Gas	
5.	*Monilia metalondinensis* Castellani ..	O	= pentoses.
	Bacillus coli sensû stricto Escherich .	Gas	
	Bacillus paratyphosus B Shottmuller ..	Gas	
6.	*Bacillus coli* Escherich	Gas	= lactose.
	Bacillus paratyphosus B Shottmuller ..	O	

URINE NOT FEHLING-REDUCING.

1.	*Monilia pinoyi* Castellani	O	= saccharose.
	Monilia rhoi Castellani	Gas	
2.	*Bacillus coli* Escherich	O	= saccharose.
	Bacillus pseudocoli Castellani	Gas	
3.	*B. paratyphosus B* Shottmüller var. M. ..	Gas	= inosite.
	B. paratyphosus A Shottmüller	O	

URINARY TEST FOR QUININE ELIMINATION.

At times it is necessary for the physician to be certain that quinine is being absorbed by the patient, and at others that the patient is really taking the quinine which has been ordered. Under such conditions a simple easy urinary test which will indicate the presence of the drug in the urine is of value. Such a test can be performed as follows:—

A. To 2 cubic centimetres of the *filtered* urine contained in a *clean* test-tube add ½ cubic centimetre of *Tanret's reagent*. This reagent is a mixture of 3 grammes of iodide of potash, 1 gramme of corrosive sublimate, and 20 cubic centimetres of glacial acetic acid, in such a quantity of distilled water as will produce in all 60 cubic centimetres.

B. If the patient has been taking quinine, or if he has albumen in his urine, the operation described in the preceding paragraph will give rise to *a faint opalescence* or *a white cloud*, depending upon the quantity of either present.

C. Next add a few drops of *absolute alcohol*, when the precipitate if due to quinine will disappear, while that caused by albumen will remain.

This reaction appears in about two hours after taking a dose of quinine, and will persist for twenty-four hours after a dose of 5 grains, and for forty-eight hours after that of 20 grains of the drug.

CHAPTER LXXXVI

DISEASES OF THE GENERATIVE SYSTEM

General remarks—Male generative system—Endemic funiculitis—Female generative system—Tropical puerperal fever—Sutika—References—Addendum—Ante- and post-natal pathology—Addendum references.

GENERAL REMARKS.

In this chapter we propose to include a few general remarks upon the male and female generative systems. The subjects will be merely touched upon, as space forbids anything else.

MALE GENERATIVE SYSTEM.

In Chapter III., p. 77, we have invited attention to the effects of climate upon the generative organs, and have noted that they act more vigorously than in the Temperate Zone, and that venereal excess is distinctly more deleterious in the tropics than in temperate climates. We have also noted that puberty in boys appears at an earlier age in the tropics than in other climates.

In Chapter V., p. 118, we have touched upon the subject of Eugenics, and have mentioned the ill-effects of *alcoholism*, *syphilis*, *gonorrhœa*, and *tuberculosis*, the effects of which are much the same as in other climates, but as regards the first we have set forth its evils in Chapter X., p. 175. In reference to syphilis, it is very common, and its primary, secondary, tertiary, and inherited effects can be abundantly seen among natives, as may be judged from Chapter XCVII. *Gonorrhœa* is very common among all classes of the population and all races. The clinical features are the same as observed in temperate zones, but complications are much more frequent, owing to the native patients consulting a doctor only when the disease is of long standing. We have seen several cases of gonococcus septicæmia with endocarditis ending fatally, and also several cases of so-called 'gonococcus rheumatism.' It may be noted that among certain natives there is a general belief that the disease is not of sexual origin. African porters firmly believe that it is due to prolonged marching. There are also various curious superstitions in connection with it. In Abyssinia, according to Annaratone, natives believe it is contracted by passing water on the ground illuminated by moonshine, or by passing water where dogs have previously urinated. Occasionally true cases of non-gonorrhœic urethritis are met with (p. 1943); in a few of these cases chlamydozoa-like bodies have been described. Rare cases of urethritis, with black discharge due to the presence of *Aspergillus fumigatus*, and cases of balanoposthitis due to monilias, are observed. *Neglected strictures* are by no means uncommon, and, as we have already stated, one of these apparently caused intestinal obstruction and death. Extravasation of urine is not rare—at all events, in Africa—as the result of neglected stricture. *Elephantiasis of the generative organs* is common in Africa, and in many parts of tropical Asia and America. *Hydroceles, chyloceles, hæmatoceles, orchitis,* and *epididymitis* are all common, and bilharziosis has been already noted by us. Epithelioma of the penis is associated with phimosis and the accumulation of irritating secretions, which may cause balanitis. In these circumstances, if no treatment is carried out, epithelioma may result. Certainly epithelioma of the penis is rare in races in which circumcision is performed.

Castration and circumcision are still performed in many tropical countries. As regards the former, it may be restricted to the simple removal of the testes, but more generally the penis also is cut away. This operation is usually performed upon small boys. Circumcision usually takes place about puberty, but in some races it is performed at an early age. It is usually associated with some semi-religious rites intended, in the case of the older boys, to be an initiation to sexual life, as may be found detailed in works upon anthropology. Christopherson has drawn attention to the mutilations performed by the Abyssinians upon their conquered foes in times of war. This consists of a complete castration—*i.e.*, the removal of the penis and testes—and, as may be imagined, but few survive such a mutilation performed on the field of battle. The result of these operations and mutilations is the formation of much scar tissue surrounding the orifice of the urethræ and the pubes.

With regard to the *breast*, we have seen extraordinary hypertrophy of the male breast.

ENDEMIC FUNICULITIS.

Synonyms.—Suppurative phlebitis of the spermatic cord, Suppurative corditis, Cellulitis of the spermatic cord, Cirsoitis (Pfister).

Definition.—Endemic funiculitis is an acute specific suppurative inflammation of the spermatic cord, of which the ætiology is not firmly established.

History.—For many years medical men practising in Ceylon have noticed the occurrence of a peculiar form of acute suppurative inflammation of the spermatic cord, which occasionally takes a true epidemic character, numerous cases occurring within a short period. References to this affection may be found in almost all the medical reports for the colony during the last twenty years, the disease being variously indicated by the name of phlebitis of the cord or corditis. It was considered by some to be of traumatic origin, by others of venereal origin. Some practitioners considered it to be a malarial affection. The disease was investigated by Castellani first in 1904, and more completely in 1907. He came to the conclusion that it had nothing to do with either malaria or gonorrhœa. He thought the malady had sufficiently characteristic symptoms to be ranked as a separate disease, and suggested the name 'endemic funiculitis.' The affection is not limited to Ceylon, as cases occur in Southern India, and an identical pathological condition has been described in Egypt by Madden in 1907 under the name of cellulitis of the spermatic cord. The condition described by Wise in the West Indies is probably the same pathological entity. Of great importance are the investigations by Coutts

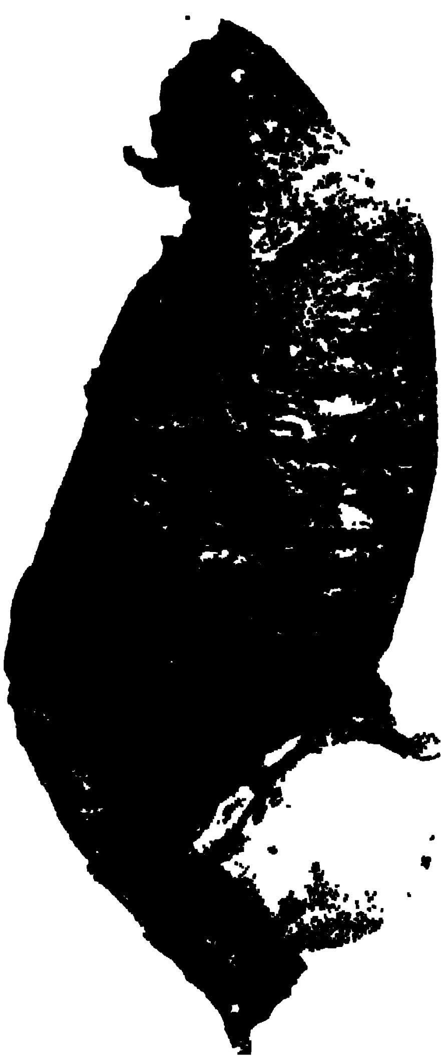

FIG. 780.—ENDEMIC FUNICULITIS, SHOWING LONGITUDINAL SECTION OF THE CORD.

The testes and epididymis are normal

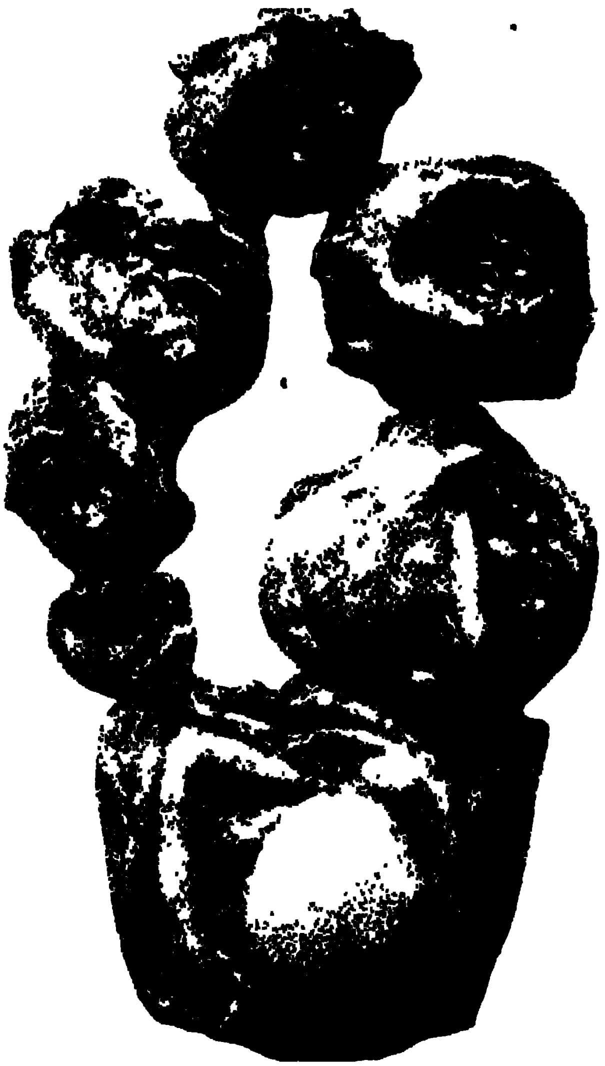

FIG. 781.—TRANSVERSE SECTIONS OF THE CORD IN ENDEMIC FUNICULITIS.

The testes and epididymis were normal, but the tunica vaginalis held a small quantity of fluid. The sections of the cord are arranged in an arch from right to left. The dilated veins, which were filled with pus, are clearly visible.

Ætiology.—Among Ceylon practitioners the disease was considered by some to be of traumatic origin; others believed it to be of venereal origin, and yet others to be a malarial affection. Castellani found in all the cases virulent diplo-streptococci, and in some cases, one in 1904 and the others in 1909, and later, a microfilaria. This microfilaria is morphologically identical with *Microfilaria bancrofti*, but in our cases, though provided with a sheath, it showed translation movements. The cocci are practically indistinguishable from the ordinary streptococci but for the fact that some decolourize by Gram in sections of the tissues and in smears from the pus, while they are Gram-positive in cultures. According to Coutts these micrococci are often found in the urethra of natives. He regards the suppurative condition of the cord as due to the extension of an infection from the urethra by way of the vas deferens. Wise has found in his cases *F. bancrofti* and numerous streptococci. Pfister believes the disease to be connected with bilharziosis. We are inclined to consider the malady to be a filarial condition with a superadded streptococcus infection The filaria probably plays the more important or only rôle in the subacute or chronic cases, while the streptococcus is probably the causative agent of the acute symptoms and the suppuration, and of the symptoms of septicæmia.

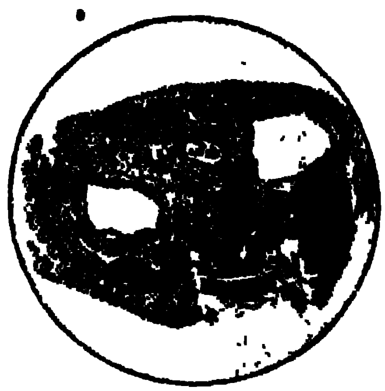

Fig. 782.—Transverse Section Inflamed Cord. (Actual Size.)

Predisposing Causes. A certain importance must be given to a sudden chill or to some form of traumatism. In nearly all the Ceylon cases the disease begins abruptly after taking a cold bath when feeling tired. In some cases the patient gives a history of having made an effort, such as in lifting a weight, etc

Pathology. The whole of the spermatic cord is highly inflamed and infiltrated. The circumference of the cord may be as much as 3 to 3½ inches. The tunica vaginalis is hyperæmic, but in most cases there is no collection of fluid. On making a transverse section of the cord, yellow creamy pus will exude from the opened veins of the pampiniform plexus, as well as from the vas deferens. The inflammation is not localized to the cord only; it ordinarily extends to the epididymis. In two very recent cases of ours, however, the epididymis was normal. The testicle proper remains generally unaffected; there is occasionally some effusion of clear fluid into the tunica vaginalis. The histological lesions are, briefly, the following: The veins of the pampiniform plexus are much dilated, and present a cellular infiltration of all the coats, the lumen of some veins being occupied by pus cells or thrombi. The vas deferens also presents a well-marked cellular infiltration of its mucous membrane and various muscular coats. The type of cellular infiltration as noted by Coutts and Castellani is mostly mononuclear.

Morbid Anatomy.—At the post-mortem examination of the cases in which an operation has not been performed in time, the lesions found are those of a septicæmic process. The skin is jaundiced, and may present petechiæ; the lungs often show hypostatic congestion: the heart is flabby, and subpericardial hæmorrhages are often seen. The spleen is enlarged and soft. The liver is generally enlarged, and may show fatty degeneration or cloudy swelling. The kidneys are often congested.

Symptomatology.—The disease begins suddenly, generally after a hard day's work or severe exercise. In Ceylon the usual history is as follows: The patient, after an extra hard day's work, comes home in the evening very tired, but not feeling unwell, and takes a cold bath as usual. After the bath he is suddenly seized with a shivering fit, the temperature rising very high. He feels very sick, and there is often actual vomiting. At the same time he complains of pain along the cord and the epididymis. The condition becomes rapidly worse, and the patient is generally taken to hospital on the second or third day of the illness. On admission, it is usually found that the general condition is grave. There may be continuous vomiting, and occasionally hiccough; the temperature is generally above 102° F., and the pulse small and frequent. At the physical examination it will be seen that the inguinal region is occupied by a large cylindrical swelling in the direction of the cord. The swelling is very tender on pressure, and hard; the skin is not affected. Generally the epididymis is somewhat enlarged and tender, though in some very recent cases it may not appear to be affected. In all cases the testicle proper appears to be normal; there is, as a rule, no effusion in the tunica vaginalis. The affection is generally localized to one side only, but occasionally attacks both sides. On examination of the penis and scrotum no ulcers will be found, no signs of gonorrhœa, and no signs of any traumatic lesions, though in several cases the patient gives a history of having made an effort of some sort. As a rule, the disease has no tendency to spontaneous recovery. If an operation is not performed in time, signs of general septicæmia usually set in. In such cases the skin of the patient often becomes jaundiced, cutaneous hæmorrhages

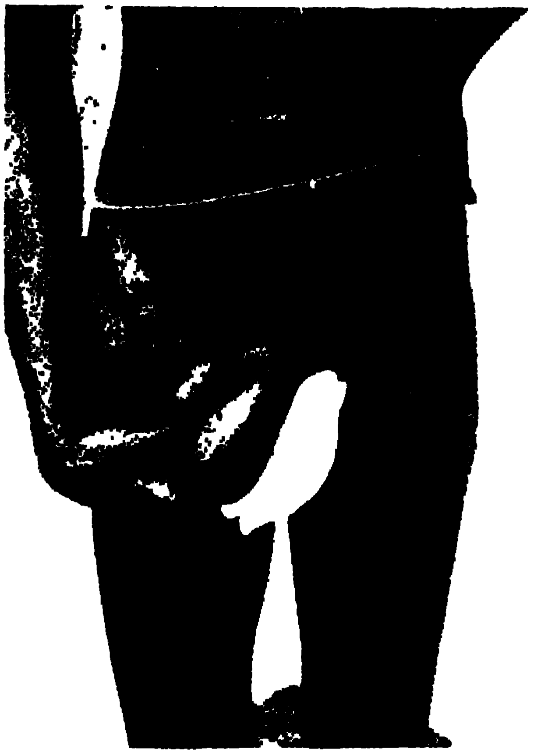

FIG. 783.—ENDEMIC FUNICULITIS IN A SINHALESE MAN.

may appear, the fever is of an intermittent or remittent type, the pulse becomes extremely small, there is often hiccough, and the patient dies in a few days.

Varieties.—A mild form, with thrombosis of the veins, but without suppuration, is at times met with. According to Coutts, a chronic form, also without suppuration, may occur.

Prognosis.—This is serious in the ordinary acute form. If an operation is not performed in time, symptoms of general septicæmia set in, and the case, as a rule, ends fatally.

Diagnosis.—The disease is apt to be confused with strangulated hernia and an acute elephantoid condition of the testicle and cord. From the former endemic funiculitis may be differentiated by the history, the high fever, and the course, which is somewhat less acute. In some cases, especially in the fulminating forms, operative treatment alone will clear the diagnosis.

From an acute elephantoid condition it may be differentiated by the absence of the erysipelatous-like redness of the skin.

Treatment.—Except in the rare mild forms, when lead lotion and ichthyol ointment, with or without ice application, may be sufficient, the only effective treatment is surgical, and orchiotomy, with section of the inflamed cord as high up as possible, is imperative. Coutts recommends exposure of the inflamed cord by a free incision through the skin and external oblique, to be followed by numerous incisions into the tumour. The wound is left open, and fomentations applied till the surface is clean. The wound is then left to heal by granulation. Coutts considers that in this way, though the testis loses its generative function owing to the obliteration of the spermatic duct caused by the inflammation, its internal secretion is unimpaired.

When the disease has extended beyond the internal abdominal ring, orchiotomy must be performed and the veins left unligatured while fomentations are applied.

NON-GONORRHŒAL URETHRITIS.

Urethral muco-purulent discharge is as a rule of gonorrhœal origin, but Castellani has called attention to a number of forms of quite different ætiology, which may be classified as follows:—

A. Traumatic Mucous Urethritis.

This occasionally arises after long and violent continued physical exercise. One is rather sceptical in admitting such a type of urethritis, and practically all the cases of so-called 'porter's urethritis' we have seen were gonorrhœal infections. Still, there cannot be any doubt that in soldiers and native porters doing long marches day after day a slight urethritis with scanty mucous discharge may occasionally develop, even in individuals who have never suffered in the past from gonorrhœa. The secretion, however, in our experience is never frankly purulent.

B. Urethritis of Hyphomycetic Origin.

The following clinical varieties may be differentiated:—

1. The discharge is black, greenish-black, or brownish-black, generally due

to fungi of the genus *Aspergillus* Micheli and *Cladosporium* Link. One of us has described some of these cases in Ceylon.

2. Discharge whitish or yellowish. Generally fungi of the genus *Monilia* and of the genus *Oidium* are found.

3. Red discharge. Generally due to a red pigment-producing monilia or cryptococcus, or to a non-pigmented monilia, and associated with red pigment-producing bacilli or cocci.

C. Urethritis associated with Animal Parasites: I. With Protozoa; II. With Animal Parasites Higher than Protozoa.

I. **Urethritis of Protozoal Origin.** - The following varieties may be distinguished:—

(1) *Urethritis associated with Flagellates.*- The flagellates found belong to the genera *Trichomonas* Donné, *Cercomonas* Dujardin, *Prowazekia* Hartmann and Chagas. In one of our cases a flagellate with four flagelli was observed. It is doubtful, however, whether the flagellates found are the true ætiological agents of the discharge.

(2) *Urethritis associated with Ciliates.*- In a case of urethral discharge in a native man we observed the same ciliate we have fairly often noticed in Ceylon in the vaginal secretion of native women.

(3) *Urethritis associated with Amœba*. We have seen several such cases. The amœbæ were of different type; in one case it closely resembled *Loeschia histolytica*.

(4) *Spirochætic Urethritis.*- This type of urethritis due to *S. urethralis* Macfie is occasionally met with. The discharge may be abundant and frankly purulent, and contains an enormous number of spirochætes. It must be noted, however, that spirochætes are not rarely found in the normal urethra, as shown by many observers and in the tropics by Mendelson.

(5) *Treponema urethritis.*- The discharge is muco-purulent and contains a large number of treponemas (*Treponema urethrale* Castellani). The organism is very delicate, stains purplish or pinkish, has numerous small spirals, all practically of the same size; length of the parasite [illegible] to 12 microns. The patient has no sign of syphilis, and Wassermann is negative. Urethral irrigation of a 1 in 20,000 solution of hyd. perchlor. cures the condition.

II. **Urethritis associated with Animal Parasites Higher than Protozoa.** —These are generally due to larvæ of flies and chance parasites setting up an inflammation of the urethra.

Balanoposthomycosis.—In 1881 Simon of Breslau first described a balanoposthitis due to fungi, and occurring in persons suffering from diabetes. It is probably the same disease as that referred to by Rollo in 1798, by Bardsley of Manchester in 1807, by Friedreich in Hanover in 1864, by Hassal in 1833, and by de Beauvais in 1874. The symptoms consist of slight itching and burning on the glans penis and on the inner aspect of the prepuce, and is associated with erythema, followed by superficial ulceration and a yellow purulent discharge, while the margin of the prepuce may become irritated and phimosis set in. On examining the discharge fungal hyphæ of a moniliform character may be seen. Castellani has described several such cases due to fungi of the genus Monilia.

FEMALE GENERATIVE SYSTEM.

Circumcision is exceedingly common among native races—*e.g.*, among the semi-civilized Arabs and the Sudanese of Kordofan and other parts of the Sudan every young girl when aged five or six years undergoes one of two varieties of this operation. The milder operation, called 'sunna tahuret,' or circumcision according to religious law, consists of the removal of the clitoris and labia minora, while the more severe cutting, called 'Pharaoh's tahuret,' or the old

Egyptian circumcision, entails in addition the removal of the upper two-thirds of the labia majora. The result of these operations is the formation of scar tissue, and hence it is almost always necessary to enlarge the vulvar orifice by means of a razor, not merely at the time of marriage, but again at the birth of a child, when, otherwise, it would be difficult for the head to emerge. The enlarged orifice is again partially closed some little time after birth of the child, and therefore incision has to be repeated at every succeeding birth.

In 1910 Wilson studied the peculiar elongation of the nymphæ found in Hottentot women, and came to the conclusion that it was largely produced artificially.

In 1917 Neve drew attention to the fact that rickets is rare in Kashmir, but that osteomalacia was common in multiparous women, in whom the first symptoms appear in pregnancy and cause the characteristic deformity of the pelvis.

We have discussed the question of the onset of puberty and the climacteric in Chapter III., p. 77, to which reference may be made. Displacements, inflammations, and tumours of the female generative organs are quite common, especially *uterine fibromata* and *ovarian cysts*. Cancer of the uterus is not rare.

VULVO-VAGINITIS.

Every type of vulvo-vaginitis met with in temperate zones is also found in the tropics, and gonorrhoeal infections are very common. It is interesting to note that we have found in the vaginal secretion practically all the organisms we have mentioned under the heading Pseudo Gonorrhoeal Urethritis, and that there are forms of vulvo-vaginitis associated with flagellates, ciliates, amoebæ, spirochætes, treponemata, and fungi, and hence it is quite possible that a certain number of cases of protozoal and hyphomycetic urethritis in man are contracted in reality by sexual intercourse.

Vulvo-vaginitis associated with hyphomycetes is far from rare, and such cases may be separated into two principal groups:—

I. Associated with fungi of the genus Aspergillus, Sterigmatocystis, Penicillium, Cladosporium, with discharge, which may be dark-brownish or black.

II. Associated with fungi of the genus Monilia and the genus Oidium, with white or yellow discharge. These cases may present two different clinical appearances: some are characterized by the presence of thrush-like membranes on the vaginal mucosa (*vaginal thrush*); others do not show any membrane on the mucosa, but the discharge is purulent and very thick. In the tropics Castellani has found fungi principally of the types *Monilia pinoyi* Castellani, *Monilia tropicalis* Castellani. In temperate zones the same observer with Taylor have found *Monilia pinoyi* Castellani, *Monilia londinensis* Castellani, *Monilia metalondinensis* Castellani, and other species.

VAGINAL PROTOZOA.

The vagina of native women may be the habitat of numerous protozoa apart from *Treponema pallidum* and spirochætes. We record the presence of the following:—

Sarcodina :—

Loeschia histolytica (Schaudinn, 1903).
Loeschia coli Loesch, 1875.

Mastigophora :—

Oicomonas vaginalis Castellani and Chalmers, 1908.
Prowazekia vaginalis Castellani and Chalmers, 1918.
Trichomonas vaginalis Donné, 1837.
Tetratrichomonas vaginæ Castellani and Chalmers, 1918.

Ciliata :—

Balantidium vaginale Castellani and Chalmers, 1918.

TROPICAL PUERPERAL FEVER.

Synonym.—Puerperal septicæmia.

Definition.—Tropical puerperal fever is an infection of parturient or puerperal women with various germs, which may cause a local septic condition or a general septicæmia.

History.—It is probable that puerperal fever has been prevalent throughout the world in all ages wherever man has roamed, but as it is conveyed from infective sources, living or dead, autogenetic or heterogenetic, by instruments or by the hands of the attendants, to the uterus of the parturient woman, it is obvious that, in those primitive tribes in which little or no aid is given to the woman in childbirth, there will be little puerperal fever, notwithstanding that her immediate surroundings may be insanitary.

Usually in non-civilized races there is less difficulty with child labour, and hence less damage to the organs of generation, and consequently a less number of portals of septic infection.

The reasons for this easier childbirth are not well known, but may possibly depend upon two factors—*i.e.*, the mother and the child. With regard to the mother, the fact that pregnancy takes place at an earlier age in the uncivilized than in the civilized, and the fact that the woman of non-civilization, from spare and hard living, is often thinner than the woman of civilization may help, even if her pelvic measurements are relatively smaller; while it is often alleged that the head of the uncivilized child is smaller than that of a civilized race, and it has even been asserted by Brooke that on an average the child weighs 1 pound lighter in uncivilized races. If these statements are correct, they will help to explain the easy child labours and the less amount of puerperal fever in those races.

When we consider old native civilizations and the Caucasian races, we find that child labour is difficult, and that assistance has had often to be rendered to the parturient woman from time immemorable, and that puerperal fever in isolated cases and in epidemics has been known for ages.

Turning to one of the old civilizations of the tropic—viz., that seen in Ceylon—these facts are well borne out by the researches of one of us in 1907 into the vital statistics of the various peoples inhabiting that island.

These inquiries showed that the deaths of women in childbirth were higher than those in Europe, and that the principal cause was puerperal fever.

When the racial incidence was investigated it was found that the sociological and hygienic factors influencing this incidence were marked, as the percentage of the total annual racial deaths attributable to childbirth and principally caused by puerperal fever was only 0·1 per cent. for Europeans, while it was 1·2 per cent. for Sinhalese, who form the bulk of the population, 0·8 per cent. for Tamils, the next largest native community, 1·1 per cent. for a mixed native and European race known as burghers, under which heading also come those inhabitants of pure Dutch descent from the settlers of two hundred years ago. Many of these burghers are very poor, and nearly all inhabit towns and mostly live under more insanitary conditions than the average European. The Mohammedan communities of Arabs and Malays have a mortality of 1·2 per cent. and 1·1 per cent. respectively.

The disease is known to have been not uncommon in Bengal since Twining wrote in 1833, while its death-rate in Calcutta for 1906-07 was 1·2 per cent. of the total deaths.

With regard to Egypt, the first medical accounts of the fever are contained in Pruner's writings published in 1847, where it is stated that it was not so common as in Europe, but an epidemic, extending from Alexandria to Luxor, is mentioned as taking place in 1844.

The peoples of the Anglo-Egyptian Sudan are peculiarly interesting from the point of view of our present study, because they contain very primitive tribes, semi-civilized natives, and civilized peoples.

As examples of the primitive tribes we may consider the Nyam-Nyam, who live in the southern part of the Bahr-El-Ghazal Province, and the Jur or Gour tribe, which occupies a limited area of that province between the River Gell and the Rumbek-M'volo road. In these tribes, according to Anderson, childbirth is usually a simple physiological process taking place for the first time when the woman is in her teens, and managed by a midwife, who is simply any other woman who has given birth to a child, and who sees that everything connected with the parturient woman is strictly clean, and placing her on a bed of freshly cut leaves, allows Nature to do the rest, with the sole exception of such rare cases as require assistance, when, according to the same authority, she calls in the aid of some small boys. Under these primitive conditions puerperal fever must be rare. The same easy childbirth can be observed among the Bedouins of Syria.

Among the semi-civilized Arabs and Sudanese of Kordofan and other parts of the Sudan every young girl is circumcised as described above. This procedure, as already stated, is followed by the formation of scar tissue, which renders it almost always necessary to enlarge the vulvar orifice by means of a razor, not merely at the time of marriage, but again at the birth of a child, when otherwise it would be difficult for the head to emerge. The enlarged orifice is again partially closed some little time after the birth of the child, and therefore the incision has to be repeated at every succeeding birth.

If this second cutting is performed carelessly and the resulting wound becomes septic, then fever ensues, and in a case of this nature we have found streptococci and other organisms. 'These people are well acquainted with puerperal fever, which they call 'el jarat,' or sometimes 'humma nafas,' or when slight they term it milk fever, or 'humma laban,' and which they consider to be transmitted from one case to another.

The civilized peoples of Khartoum and Omdurman, more especially the Greeks, Syrians, and better-class natives, suffer from *febris puerperalis* and *febris in puerperio*, but no statistics are available to show the incidence of the disease.

As regards Zanzibar, the deaths from puerperal fever are given as eight out of a total mortality of 1,022, of which 572 are female deaths at all ages.

In none of the above statistics is it possible to compare the puerperal deaths with the number of births, as these were not accurately known.

In the West Indies and in Central and South America the fever is not uncommon, and Brooke, writing in 1908, with his experience of the West Indies and Singapore, says:

> 'The mortality and morbidity from puerperal sepsis and the infantile death-rate among native communities are enormous.'

He blames the village midwife or handywoman, who he says, is a prejudicial, ignorant, and dirty person, and summarizes his remarks by stating:

> 'We see that, for the n [illegible] woman under her native skies, want and poverty may play havoc with t [illegible] uld that is to be, but there is often a physical environment of ignoranc [illegible] sepsis during labour which demands the attention of public opinion.'

Our experience in various tropical and subtropical regions supports these statements made by Brooke.

Ætiology.—Early in the seventeenth century there appeared the idea of a double origin for the fever—viz., the autogenetic and the heterogenetic—and also that the disease was microbic in origin (Kircher, 1671).

In 1788 Denman observed that the disease was carried from cases of puerperal fever to healthy lying-in women by doctors and midwives, which view was strongly supported by the work of Alexander Gordon in Aberdeen in 1795, and by Oliver Wendell Holmes in America in 1843, the last-named observer asserting that not merely could it be conveyed in this manner, but that it could come in a similar way from a case of erysipelas or from a post-mortem, and that it was necessary for the physician to disinfect his hands and to change his clothes after leaving a case of puerperal fever. This work was ably supported and put upon a sound basis by Semmelweiss, whose brilliant researches are too well known to require recapitulation.

With these investigations the heterogenetic origin of the disease was firmly established, and it now remained for the bacteriologists to show the nature of the infective material which, when carried from the sick to the healthy, produced the disease.

In 1871 von Recklinghausen found micrococci in the bodies of persons dying from puerperal fever. The next important step was the discovery by Pasteur in 1878-79 of his 'microbe en chapelet' in the blood of puerperal fever patients.

As this organism belonged to the genus named streptococcus by Billroth, in 1874, Arloing gave it the name *Streptococcus puerperalis*, in 1884, apparently believing that it was distinct from the organism named *S. erysipelatos* Fehleisen, 1883, which is more popularly known as *S. pyogenes* Rosenbach, 1884. Later Furneaux-Jordan and Mackay have revived *S. puerperalis*, but Arloing's name has priority and stands for a synonym of *S. erysipelatos*.

A new phase of the bacteriological history was opened in 1893 by Veillon finding an obligatory anaerobic micrococcus in such diseases as Ludwig's angina, suppuration of Bartholin's glands, phlegmonous perinephritis, etc. This organism, which he called *Micrococcus fœtidus* Veillon, 1893, though usually a diplococcus, can exist in short chains, and therefore may well be a streptococcus. Hallé, in 1898, found it in the secretions of the normal vagina as well as in pus from Bartholin's glands and in the exudate of retained placentæ. It was next observed by Jeannin in 1907 to be present in numerous cases of putrid puerperal infection, and is thought by Veillon's pupils to be the same organism as the anaerobic streptococcus found in vaginal secretion in 1897 by Menge and Kroenig, whose work had been questioned by Koblank but supported by Natvig, Schottmüller, and Hamm.

In 1907 Gioelli reported the presence of a coccus, thought to be a staphylococcus, which he found in a peri-uterine abscess and named *Coccus anaerobius* Gioelli, 1907, while in 1908 he dealt with the question of the bacteriology of puerperal infections. As this coccus produces fœtid gas it may well be the same as Veillon's organism.

In 1910 Schottmuller increased our knowledge as to the streptococci in puerperal fever by finding a new obligatory anaerobe, which he called *Streptococcus putridus*, and which he found not merely in puerperal fever, but also in otitis media, meningitis, cysto-pyelitis, abscess of the lung, gangrene of the lung, and empyema, and he followed this up in 1911 by two papers upon the ætiology of *febris puerperalis* and *febris in puerperio*.

In fifty cases of *febris puerperalis* he found the following organisms to be present thirty-three times—*i.e.*, in 66 per cent., and in all severe and fatal cases:—

S. erysipelatos Fehleisen, 1883, in fifteen cases in the uterine discharges and in two of these also in the peripheral blood. *S. putridus* Schottmuller, 1910, in fifteen cases in the uterus, including five blood infections. *S. erysipelatos* with *S. putridus* three times in the uterine discharge, with both together in the blood once and separately in the other two cases.

He also met with *Streptococcus mitior seu viridans*, an aerobic organism first described by himself in 1903, in the uterus and blood of one case.

He considers that there are two distinct methods of infection: the first is the autogenous, caused by organisms, like *S. putridus*, which lives in the normal vaginæ of pregnant and puerperal women, and are capable of being carried from the vagina to the uterus by means of instruments or by the hand. This form he considers to be non-contagious.

The second method of infection is the heterogeneous, caused by *S. erysipelatos*, and brought from an external source of infection to the puerperal woman as just described.

Von Lingelsheim, in 1912, considered that the importance of *S. putridus* must, for the time being, remain undecided, as it lacked confirmation, but it is obvious that the gas production alone differentiates this streptococcus from *S. erysipelatos* Fehleisen, and it appears to us that there is a general agreement between Schottmüller's organism and that described by Veillon. They both produce fœtid gas, they both are obligatory anaerobes, and they are both found in the vagina and also in association with puerperal fever, and they have both been found in severe infections in other parts of the body. They are probably the same organism as the anaerobic vaginal streptococcus described by Menge and Kroenig, and also that found by Gioelli in 1907.

All these organisms, in our opinion, should be classified under the name of *S. fœtidus* Veillon, 1893.

In 1901 Lewkowicz found an obligatory anaerobic streptococcus, which he named *S. anaerobius micros*, in the mouths of sucklings. In 1907 Jeannin reported that it was present fairly frequently in puerperal infections. It is described as being lanceolate and usually disposed in diplococcal forms, and only occurring in short chains.

In 1812 Furneaux-Jordan published an important lecture upon 'Puerperal Infection.' He and Mackay examined the uterine discharges of twenty-one cases of puerperal fever, and found streptococci in seventeen cases—*i.e.*, 80 per cent. This streptococcus was identical in all cases, and was said to be quite distinct from other streptococci, and so the name *Streptococcus puerperalis* Furneaux-Jordan and Mackay, 1912, was given to it; but we have noted that Arloing had already applied this name in 1884 to a streptococcus which he obtained from cases of puerperal fever, and which he believed to be distinct from *S. erysipelatos* and *S. pyogenes*, the only named forms at that time, but at present all three are considered to be one and the same organism.

In 1916 Chalmers and Atiyah found that *S. salivarius*, *S. bovis* (synonym, *S. bovinus*), and *S. versatilis*, were causal germs in the Anglo-Egyptian Sudan, and traced the origin of these germs to human saliva (*S. salivarius*), zibla—*i.e.*, horse-dung used for walls and floors—bovine fæces, and equine fæces, etc. (*S. bovis* and *S. versatilis*).

The known puerperal streptococci are therefore:—

1. *S. erysipelatos* Fehleisen, 1883.
2. *S. fœtidus* Veillon, 1893.
3. *S. anaerobius* Lewkowicz, 1901.

4. *S. mitior* Schottmüller, 1903.
5. *S. puerperalis* Furneaux-Jordan and Mackay, 1912.
6. *S. salivarius* Andrewes and Horder, 1906.
7. *S. bovinus* Broadhurst, 1915 (synonym, *S. bovis* Chalmers and Atiyah, 1916).
8. *S. versatilis* Broadhurst, 1915.

Other Organisms.—Streptococci are, however, by no means the only organisms found in puerperal fever, as the following have also been recorded: *Aurococcus aureus* (Rosenbach, 1884); *Albococcus tetragenus* (Gaffky, 1884); *Diplococcus pneumoniæ* (Weichselbaum, 1887); *Diplococcus gonorrhœæ* (Bumm, 1885); *Bacillus coli* (Escherich, 1886); but *Bacillus typhosus* (Zopf, 1885) (Eberth's bacillus) only rests under suspicion, while *B. pseudodiphtheriticus* has also been reported.

Among the anaerobic organisms other than streptococci the following have been met with in puerperal infections: *Bacillus emphysematosæ* (Fränkel, 1893); *Bacillus tetani* (Flugge, 1886); and a vibrio described by Curtis in 1913, and probably by Kroenig in 1895, which, though deserving of a definite appellation, is still unnamed.

Abortion.—A very interesting point is the question whether the same organisms are found *post abortum* as *post partum*. This was investigated by Schottmuller in 1911, more particularly in criminal abortions, with the result that he found the following organisms arranged in order of frequency to be present: *S. putridus*, a *Staphylococcus*, *B. coli*, and *B. emphysematosæ*, while *S. erysipelatos* was relatively rarely met with.

Febris in Puerperio.—Another point of interest is the organisms causing *febris in puerperio*—*i.e.*, the slight fever known by Willis' name of lacteal or milk fever, which is frequently met with *post partum*. This has also been investigated by Schottmuller and Heymann, who found the following germs to be present: *S. putridus*, a *Staphylococcus*, *B. coli*, *B. erysipelatos*, *B. vaginæ*, and *B. emphysematosæ*, arranged in order of frequency.

Thus it would appear that the same organisms occur in the mild and in the severe infections, a fact which places on a sound basis Willis' observation that the mild lacteal may become the severe putrid fever.

Methods of Infection.—Adverting to the methods of infection of the parturient woman, we note that Geddes in his 'Statistics of Puerperal Fevers,' published in 1912, says that he believes 99 per cent. of the cases are due to those conducting the labour. A statement of this nature makes it imperative to possess some knowledge as to the presence or absence of bacteria in the normal vulva, vagina, and uterus.

This has been investigated by many workers whose researches make apparent that the vulva at birth is germ free, but after seven to eight hours it contains micro-organisms which have probably been acquired from the secretion of the mother's vagina, the air, and the water of the first bath. As a rule the following organisms are described as being present in the normal vulvar secretion: *Obligatory aerobes*: *Albococcus tetragenus*, *B. coli*, and *B. pseudodiphtheriticus*. *Aerobes and facultative anaerobes*: *Albococcus albus* and *B. vaginæ*. *Obligatory anaerobe*: a *Streptococcus*, probably *S. fœtidus*.

With regard to the vagina this appears to be free from micro-organisms at birth, at which time its secretion is acid, which is said to be due to carbonic acid, and is also bactericidal, an action which cannot be due to leucocytes, which are normally absent.

Some twelve hours after birth the first bacteria can be found therein. The secretion remains acid during life, but is now due to lactic acid, which is said to be present in a strength of 0·4 per cent., and appears to be associated with an organism, *Bacillus vaginæ* Döderlein, 1893.

The normal adult secretion has a bactericidal action when tested against staphylococci, streptococci, and bacteria, but saprophytic organisms can grow therein and may be obligatory or facultative anaerobes, but are generally characterized by having acidophile tendencies. Anaerobic organisms are common, but obligatory aerobes are not frequently met with. Pathogenic organisms are relatively seldom found in the normal secretion, being generally *Staphylococci*, *B. coli*, and *B. pseudodiphtheriticus*.

With regard to the normal vaginal secretion during the puerperium, its bactericidal powers are markedly increased by the lochia, and they do not return to normal until several days after the birth of the child. Notwithstanding this fact, obligatory and facultative anaerobic streptococci, staphylococci, and bacteria are to be found, as has already been indicated, and this fact appears to us to be of the greatest importance when considering the method of infection of puerperal fever.

The secretion of the normal uterus is, by a consensus of opinion, considered to be sterile.

It would thus appear as though Geddes was correct in throwing the responsibility of puerperal infection upon the attendants, as both autogenetic and heterogenetic infections are probably due to them in some way, but the former is much more difficult to prevent than the latter.

With regard to the latter, the researches of Chalmers and Atiyah have thrown suspicion upon cow and horse dung as sources of infection, and this has been confirmed by the work of Chalmers and Marshall, who found the same organisms in bovine and equine fæces.

There are three native uses of cow and horse dung, and they are:—

1. *Cow-dung Poultice.*—This is commonly used by natives throughout the Sudan, and is placed on any painful region of the body, and is, at times, applied to the lower part of the abdomen and even to the external genitalia of the pregnant woman, and in this way may bring about an infection of the vagina with bovine types of streptococci.

2. *Cow-dung Wash.*—In many parts of the tropics it is not uncommon for the natives to use a cow-dung wash for the floors and walls of dwelling-rooms for the purpose of keeping away biting insects and also white ants, and although the practice does occur in the Anglo-Egyptian Sudan it is not so common as in other parts of Africa and in parts of Asia.

Cow-dung, however, is used in Khartoum and Omdurman as a wash for the tops of ovens, and especially of those used for baking bread, and also for the walls of outhouses, especially those used for storing grains.

3. *Zibla.*—It is also used at times in lieu of horse-dung as a constituent of a mixture called zibla which is applied to roofs and walls.

As this wash dries it must form dust, which must pollute the air and be driven hither and thither by the strong winds, which are often present in certain areas of the Sudan, and as the researches of Andrewes and Horder have demonstrated that streptococci are resistant to desiccation, it is possible that the dust derived from dried cows' dung may contaminate the sterile instruments and hands of the attendants on the parturient woman, and so bring about puerperal infections, which would belong to the heterogenetic type.

Once the disease has been started it is always possible for new cases to be infected from previous cases by the agency of attendants, and in this way an epidemic may arise at any time, or, failing this, the infections may be kept up indefinitely by the same means.

Pathology.—The post-mortem anatomy shows some of the features well known in Europe.

Symptomatology.—There seems to be no doubt that the same organisms can cause the mild 'febris in puerperio,' and the severe 'febris puerperalis.'

Why there should be such a difference is not clear, and must depend in some way or another upon the general bodily condition of the patient, and perhaps upon the strength of the streptococcal strain, which, as is well known from laboratory experiments, varies considerably.

Be this as it may, there can be no doubt that one and the same organism infecting the uterus can cause the mild 'febris in puerperio' or 'milk fever' and the more severe and even fatal 'febris puerperalis,' the symptoms of which vary according as to whether there is a local, more or less extensive infection, or a septicæmia.

Prognosis.—A prognosis may be arrived at by observing improvement or the reverse in the clinical symptoms, but more accurate decisions may be deduced by a study of the opsonic indices taken daily, provided that the causal organism is known and is available in pure culture, the index, as already stated, remaining low or sinking in serious or fatal cases, but rising as improvement sets in.

Diagnosis.—It is of the utmost importance that any fever attacking a puerperal woman in the tropics should be assumed to be puerperal fever until it is proved to be something else.

The presence of one of the varieties of puerperal fever can be confirmed:—

1. By microscopical examination of stained smears of the intra-uterine exudate taken aseptically by a sterile swab passed through a sterile speculum inserted into a previously douched vagina.
2. By cultural examinations in ascitic broth of the same exudate taken in the same way, and incubated aerobically and anaerobically at 37° C. and examined at the end of twenty-four and forty-eight hours.
3. By a low opsonic index in the case of the streptococcal infections as tested against the causal organism. This of course is especially applicable in small or large local epidemics, when the causal organism will be available in pure culture in the local bacteriological institute.

With regard to the differential diagnosis, the most important fever which requires attention is malaria occurring in the puerperium, and this should be capable of easy differentiation by:—

1. An examination of peripheral blood smears for the parasites, or, if they cannot be found, by—
2. A differential leucocytic count, with the discovery of a distinct mononucleosis which cannot be explained by other protozoal infections, such as amœbic dysentery, kala-azar, etc.
3. Enlargement of the spleen, not due to one of the forms of tropical splenomegaly.

If these three tests fail to decide the presence or absence of malaria, then a few doses of quinine should be administered, and can do no possible harm, and may even benefit the patient if a puerperal infection due to streptococci or bacteria is present. In our experience this quinine is best administered by intramuscular injections, with or without oral administration, and should, in nervous patients, be associated with a dose of sodium bromide. If the temperature rapidly declines and the symptoms improve with the quinine therapy, then the diagnosis of malarial fever may be made, but if, as has more often happened in our experience, the fever continues, then the disease is not solely caused by malarial parasites. If there is reason to suspect that the puerperal fever is septicæmic in type, or if early enteric fever in its broadest sense is feared, then the diagnosis can be effected by removing aseptically 1 c.c. of peripheral blood from a vein and immediately adding this to nutrient broth medium contained in a flask, half of which is then incubated aerobically at 37° C., while the other half is incubated anaerobically at the same temperature, and both are examined at the end of twenty-four and forty-eight hours.

By these methods, and by these alone, as far as our experience goes, can a case of puerperal fever be accurately diagnosed.

Treatment.—The aim of the rational treatment of puerperal fever must be to:—

1. Kill the causal organisms.
2. Neutralize their toxic effects.
3. Promote the normal action of the patient's organs.

In order to kill the causal organisms they must be attacked in the positions in which they are living, and as this is usually the wall of the uterus, it is necessary to give the patient an anæsthetic as soon as possible and to thoroughly investigate the walls of the uterine cavity in order to discover any portions of placenta, membranes, or blood-clot, and at the same time to observe whether there is any abscess formation in the vicinity of the uterus and also whether there is any inflammation of the tubes, both of which conditions being treated if present.

Usually all that is necessary is the removal of offending substances from the uterus by means of a mild and modified form of curettage, followed by a thorough antiseptic irrigation of its cavity, which is then drained.

After this the vagina and uterus should be irrigated twice or three times a day with an antiseptic solution in bad cases, and less frequently in mild cases.

With reference to the second heading, viz., the toxic effects of the organisms, if these are at all marked they should be combated at once by means of injections of antistreptococcal serum if these are the causal organisms, and by saline, subcutaneous, or intravenous injections, which should be given early and not reserved until too late for beneficial results to follow.

The third point is a matter of common knowledge, and need not delay us here.

SUTIKA.

Synonym.—The puerperal diarrhœa of Bengal.

Under the above term Dr. Pearse, the Medical Officer of Calcutta, gives an account of a chronic diarrhœa associated with fever which causes a death-rate of 1·3 per cent. in the total number of registered births in Hindu and Mohammedan puerperal women of all ages in that city.

The disease begins with diarrhœa some two or three weeks after delivery, there being five to fifteen watery, frothy, fermenting motions per diem without blood or mucus. Along with the diarrhœa there may be loss of appetite and dyspeptic symptoms, rarely vomiting, but no griping pains or abdominal tenderness. The temperature is raised, and an irregular fever lasts throughout the illness. There is no vaginal discharge; œdema of the feet is noted as a late symptom. The course of the disease varies. Sometimes it is rapid, and kills the patient in a few months: more usually it lasts five to eight months, and less usually it continues for more than twelve months. Towards the end the patient becomes weak and emaciated, and dies of exhaustion. The case-mortality is not known.

The nature of this disease is obviously obscure, and requires investigation.

ADDENDUM.

REMARKS ON ANTENATAL AND POSTNATAL PATHOLOGY.

General remarks—Antenatal pathology—Postnatal pathology—References.

General Remarks.

We think that perhaps a few remarks concerning antenatal and postnatal pathology may be of interest.

Antenatal Pathology.

Much useful work has been done of late in Calcutta and other tropical towns by means of *lady health visitors*, by the training and provision of *midwives*, as well as by the training of school-teachers and school-girls in matters connected with hygiene. The effect of skilled attention at the time of birth has been indicated by the entire absence of *tetanus neonatorum* amongst babies delivered by the municipal midwives in Calcutta, and by the extraordinarily low death-rate under similar conditions during the first week of life, as related by Miss Lewis.

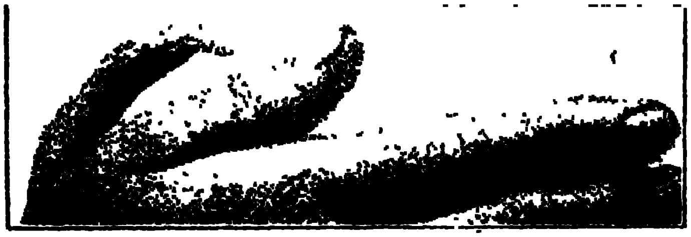

FIG. 784.—POLYDACTYLISM.

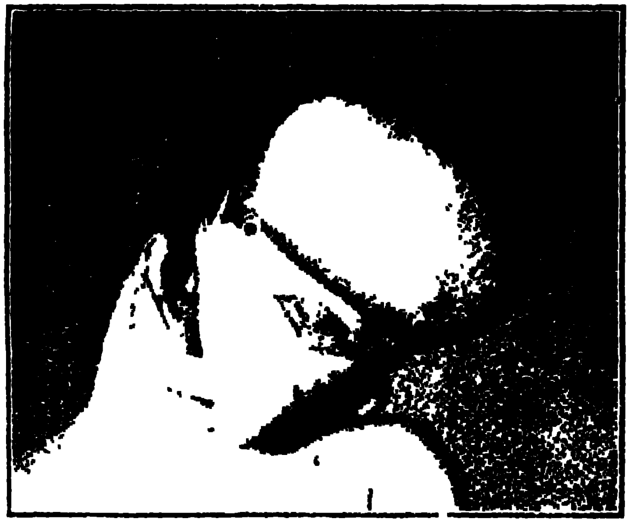

FIG. 785.—CYCLOPS.
(From a photograph by Sambon.)

There can be no doubt that this is the right step to combat such diseases as puerperal fever and infantile mortality, but in order to insure the birth of a healthy child the mother should be medically advised in the early days of pregnancy, and suitable medicines given, if necessary, as so many monstrosities and abnormalities appear in the tropics that some care is required to diminish their numbers.

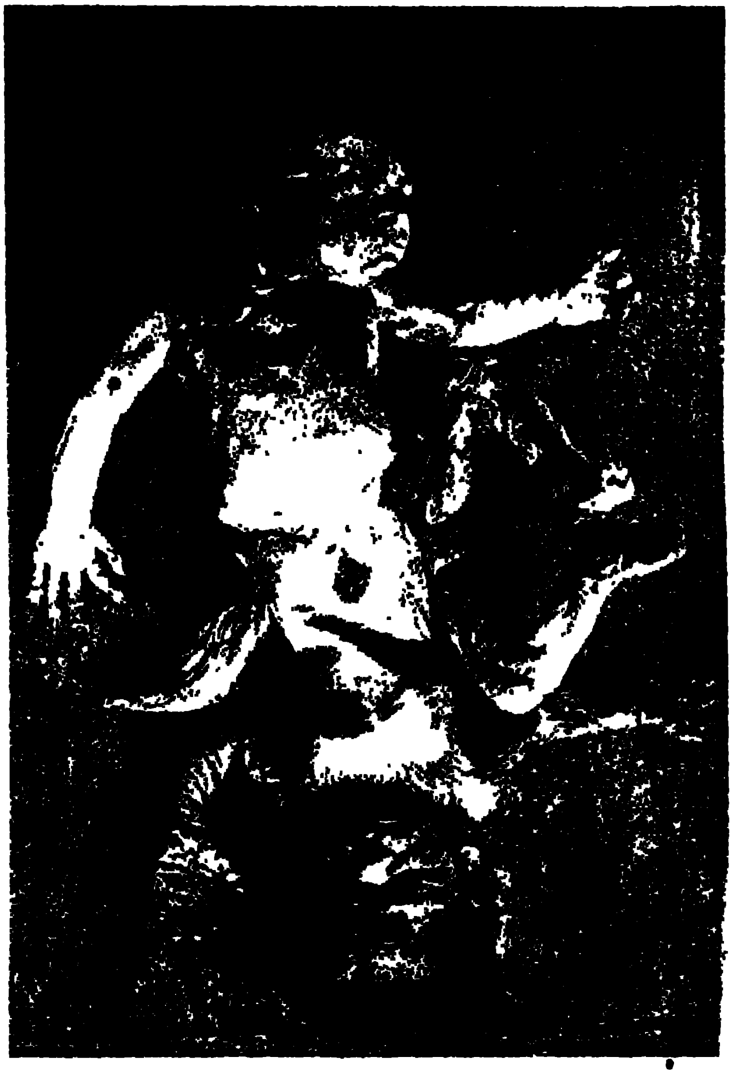

FIG. 786.—ISCHIOPAGUS TRIPUS.

Since the days of Licetus many attempts have been made to classify monstrosities by such authorities as Buffon, Blumenbach, Meckel, Bischoff, Foerster, Fischer, Ahlfield, and others, while Ballantyne has written a most interesting book on the subject.

We have always used the classification introduced by Hirst and Piersol in 1892, and have found it useful. It is as follows:—

Hemiterata.—Anomalies of volume, form, colour, structure, disposition, number, and existence.

Heterotaxis.—Splanchnic inversion and general inversion.

Hermaphrodites.—True, including bilateral, unilateral, and lateral, and false —*i.e.*, with double sexual external genitalia, but unisexual glands.

Monsters.—These are divided into:—

A. *Single monsters* :—

I. Autositic:—Ectromelus, Symelus, Exencephalus, Pseudencephalus, Anencephalus, Cyclocephalus, and Otocephalus.

II. Omphalositic:—Paracephalus, Acephalus, Asomata, and Anideus.

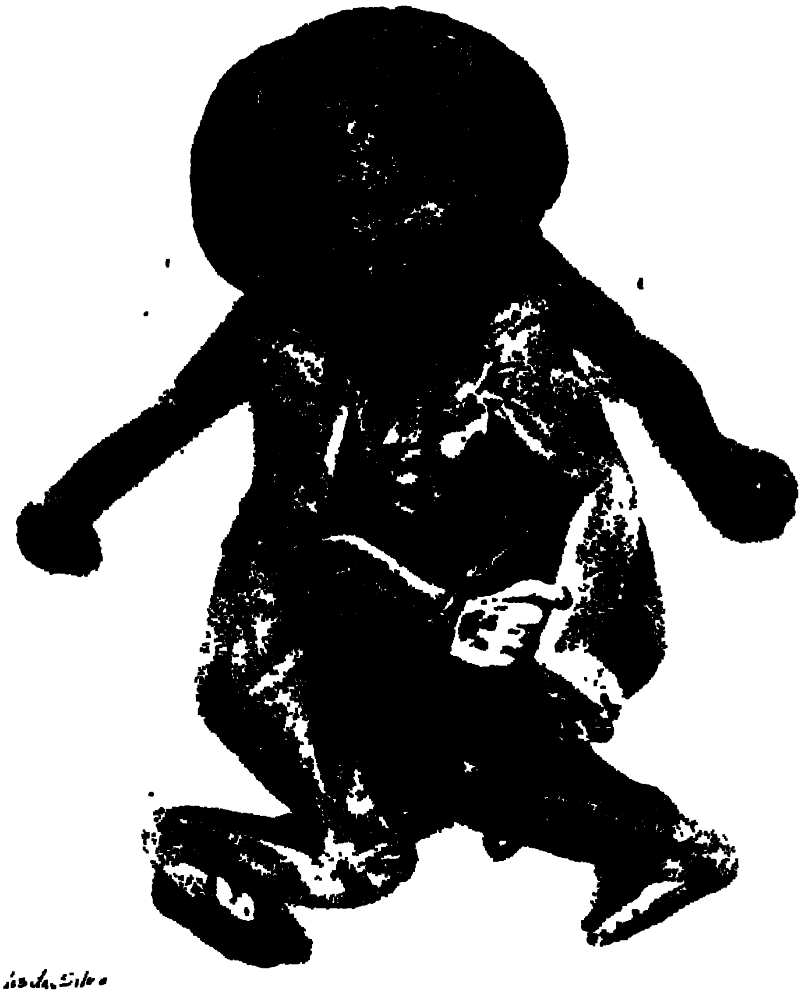

FIG. 787.—SYNCEPHALUS OR JANUS.
(This form of monster is fairly common in Ceylon)

B. *Composite monsters* :—

I. *Double autositic* :—

(*a*) *Terata katadidyma* :—Diprosopus, Dicephalus, Ischiopagus, Pyopagus.

(*b*) *Terata anadidyma* :—Dipygus, Syncephalus, Craniopagus.

(*c*) *Terata anakatadidyma* :—Prosopothoracopagus, Omphalopagus, Rachipagus.

II. *Double parasitic* :—Heterotypus, Heteralius, Polygnathus, Polymelus, and Endocyma.
III. *Triple monsters.*

Fœtal monstrosities and *abnormalities* appear to be much commoner in the tropics than in the other parts of the world, or else we have been singularly fortunate in meeting with them. This is hardly the place to give a detailed account of these abnormalities, but we should advise the tropical practitioner to have some elementary ideas, at all events, on the subject, and therefore we indicate in the above classification the varieties known and in the references the works dealing with this subject. We have met with the following:—Fœtus papyraceus, cyclops, agnathia; several double monsters of both general types, including a specimen of symmetrical janus; acephalic monsters; and rachischisis, meningocele, non-development of the eye, coloboma iridis, hare-lip, cleft palate, branchial fistula, non-development of the thigh. Macrodactylism has been reported from the Philippines, and pes gigas from China.

Further, McCarrison and others have shown that endemic cretinism is brought about by goitre in the mother, combined with psychic impressions or illnesses during the pregnancy, as well as with nutritional difficulties and difficult labour; and it should be the duty of the Government of districts in which goitre is endemic to take steps to combat these factors.

Postnatal Pathology.

The infantile mortality of the tropics is much higher than that in the Temperate Zone, and must be combated by 'Baby Welfare Work,' as in Europe, with a 'Baby Clinic' in all the hospitals. In Calcutta daily visits are paid by the midwives during the puerperal period, and then the work is carried on by the lady health visitor by weekly visits until the child is three months old. Among other matters, the feeding of the mother is attended to by organized private charity. A pure milk supply is an essential in every community, and should be under Government control and at a cheap rate.

Meningitis is rare among the newborn, and seems, according to Barron, to be mostly associated with spina bifida and to be caused by *Bacillus coli*, *staphylococci*, *streptococci*, and more rarely by the *pneumococcus*, the *meningococcus*, *B. lactis aerogenes*, or *B. pyocyaneus*; but of all, *B. coli* is the most important according to him. Breast-feeding is most important, and it may be that it helps to raise the resistance of the infant against disease.

Weaning is a difficult and dangerous period in the tropics, and it is considered that if possible a child should not be weaned in the very hot weather.

In calculating out the dilutions necessary for cow's milk it will be remembered that the milk of the *Bos indicus*, the humpbacked cow, is very rich in fat, attaining generally about 5 per cent. thereof.

The great danger of this period is diarrhœa or dysentery from infections with amœbæ or bacilli.

All the diseases which attack adults in the tropics may affect the child after birth, and the special features which they show have already been recorded, as well as the treatment, in the chapters on the various diseases, and need not be repeated; but the danger of the child being infected with tuberculosis is very great, especially in the slums of large towns

Dosage of Drugs.—As we have often been asked for the dosage of drugs in young children, we give the following rules:—Several drugs, but especially opium, require to be given with caution, as children are especially susceptible to them; but excluding these, the best method so far published for the determination of dosage by age is Cowling's rule with Brunton's modification.

In brief, it is to take the full adult dose and divide it by a factor obtained by placing the child's age at its next birthday over twenty-four if the ordinary British weights and measures are used, and over twenty-five if the metric system be employed. For example, suppose that the full adult dose is 6 grains and the child's age next birthday is four years, then the factor is $\frac{4}{24}$ (*i.e.*, $\frac{1}{6}$) and the dose is 1 grain.

CHAPTER LXXXVII

DISEASES OF THE LYMPHATIC SYSTEM

General remarks—Climatic bubo—Volvulosis—References.

GENERAL REMARKS.

The lymphatic system is affected in many general diseases—as, for example, in plague and trypanosomiasis—and in cosmopolitan affections like septic disease, syphilis, tuberculosis, etc. In addition, there is the enlargement of the glands in the inguinal region called 'climatic bubo,' and the various pathological phenomena caused by *Filaria bancrofti*. These morbid changes are varices of lymph-channels, inflammations, and elephantiasis, and have already been discussed in the chapter on Filariasis. The pathological changes caused by *Onchocerca volvulus* must be mentioned here.

With regard to the serous membranes, pleurisy and empyema are common, while peritonitis from the perforation of a typhoid ulcer or the perforation of the bowel by an *Ascaris*, as has been recorded by Ziemann in the Cameroons, or from the extension of some septic area—*e.g.*, a gonorrheal salpingitis—are all met with. Chylous ascites is rare.

CLIMATIC BUBO.

Synonym.—Glandula idiopathica (Brooke).

Definition.—Climatic bubo is the enlargement of the inguinal glands associated with pain and fever, the cause of which is unknown.

History.—The history of this disease only dates back to 1896, when Ruge reported several cases suffering from inguinal buboes, in which the usual causes of such an adenitis were all absent, and he was therefore inclined to consider the disease a separate entity dependent probably on climatic influences. About the same time Goding, independently of Ruge, published a series of observations apparently of the same nature, while more recently cases have been reported by many observers.

The disease has been recently investigated by many observers—*e.g.*, Rüffer, Luzzatti, Vanzetti, Rost, Nattan-Larrier, Letulle, Ley, and others.

Climatology.—The chief geographical distribution of climatic bubo is the East Coast of Africa, the West Indies, the Straits Settlements, and China, but it may be met with in any tropical and subtropical region. Le Dantec quotes cases occurring in Mauritius, Tonkin, and Madagascar. Low and Castellani have described a case in Uganda, while Luzzatti has met with several cases in Chili. We have observed cases in Ceylon, and Skinner has described numerous cases in Bengal. Climatic bubo may also occur in the Temperate Zone, for Scheube has come across several cases in Japan, Gabbi in Sicily, and Rost in other Mediterranean districts.

Ætiology.—Though various micro-organisms have been described, the ætiology of the disease is still obscure.

Ferraro, from one of his cases, isolated an organism practically identical with *Bacillus pestis*. Hewlett isolated from the affected gland a bacillus not decolourized by Gram, the characters of which were somewhat similar to those given by Kitasato in his first description of *B. pestis*; for Kitasato stated at first that the *B. pestis* was not decolourized by Gram. Low and Castellani were not able to grow any organism from their case. Some authors have isolated the ordinary pyogenic cocci.

Martin, Suger, Le Sueur, and Fleurant consider climatic bubo to be a manifestation of malaria. Schumm believes the bubo to be secondary to some intestinal infection G. Rost believes the affection to be of sexual origin, and due to a micro organism living in the vaginal mucosa of native women.

According to Cantlie, climatic bubo is a form of attenuated plague—*Pestis minor*—basing this opinion on the fact that in Hong Kong he observed several cases of so-called climatic bubo to precede the outbreak of an epidemic of true plague. He has been confirmed in his opinion by Hewlett's discovery mentioned above. Cantlie's theory is supported by Luzzatti, who considers the climatic bubo to be a form of *Parapestis*. Ernest Black suggests that the disease may be due to an insect bite.

Letulle and Nattan-Larrier have seen in the cells of the capillaries minute bodies which they believe to be parasitic

In our opinion, climatic bubo is a disease *per se*, and is not related to plague.

Predisposing Causes.—The condition is apparently most commonly met with in sailors and stokers. It occurs chiefly in young adults, and is said never to be found in children.

Pathology.—The results of our histological researches agree better with those obtained by Vanzetti in Italy on the material collected in South America by Luzzatti than with those of other authors.

The capsule of the affected gland is much thickened, and the interstitial tissue is very abundant. There is great proliferation of lymphocytes, and hæmorrhagic foci are noticeable here and there. Very characteristic is the presence of numerous typical plasma cells, while the so-called retractile Recklinghausen cells found in plague are absent. The histological structure of climatic bubo is, therefore, totally different from that of the plague bubo, in which, as was shown by the classical histological investigation of Duerck, plasma cells are absent or extremely rare, while the so-called retractile Recklinghausen cells are numerous.

Symptomatology.—The length of the incubation is not known, but according to some observers it may be prolonged. Ley and Rost believe that it can extend to many weeks. The onset is generally gradual; after perhaps two or three days of vague malaise and slight fever, the patient complains of pain in one or both of the inguinal regions, which increases on walking. On examining the parts, one or more inguinal glands, or occasionally the crural glands on both sides, or more frequently one side only, will be found to be enlarged, very painful on pressure, and hard. The swelling may be as large as a goose's egg. There will be no signs of lymphangitis present. The glands may become greatly enlarged, reaching the size of a hen's egg or larger, but in most cases do not suppurate. Aspiration by means of a syringe will draw only a little gland-juice, occasionally blood-stained, but no pus. The liquid will be found to be sterile.

Fever is often present of an irregularly remittent or intermittent type. It rarely exceeds 102° F.; and is higher at night than in the morning. The duration of the disease is variable, from a few days to several weeks, and rarely months. In time the pain in the affected region gradually disappears, the size of the enlarged glands decreasing. As a rule, the affected glands remain larger than normal, but not painful, long after the illness is over. Occasionally a relapse occurs. The general health is not much affected, though the patient may be very weak and unfit for work. The spleen is not enlarged. The examination of the blood may reveal a slight leucocytosis; Wassermann's reaction is negative; the urine is normal. Occasionally a trace of albumen may be present.. Intestinal symptoms are generally absent.

Clinical Varieties.--In our experience an acute, a subacute, and a chronic type of climatic bubo may be distinguished. *The acute type* is always accompanied by fever and severe pains in the affected glands. All the symptoms disappear within five to ten days. In *the subacute and chronic type* lasting from a few weeks to several months the onset may be insidious, without any local pain at first, and fever may be absent altogether. Moreover, in some cases the periglandular tissues become inflamed, suppuration may take place, and fistulous tracks may develop.

Diagnosis.—The absence of soft chancre on the genital organs will exclude *venereal bubo;* the absence of lymphangitis, infected wounds, insect-bites on the legs and feet will exclude the ordinary symptomatic bubo. In contrast to *plague*, the patient does not look very ill, but the only satisfactory way to differentiate acute climatic bubo from a mild case of plague is the puncture of the affected glands and the bacteriological examination of the gland-juice. To do this the skin of the inguinal regions is thoroughly cleansed with spirit and ether, then disinfected with a perchloride (1 in 1,000) or carbolic lotion (5 per cent.), then washed again with ether or spirit, or more simply the skin may be painted with tincture of iodine. One of the enlarged glands is then aspirated with a sterilized syringe. The gland-juice which is drawn off is then examined microscopically and by culture method in the ordinary way for the presence of the plague bacillus.

Climatic bubo is generally easily distinguishable from attacks of *filarial lymphadenitis*, which is generally accompanied by very high fever and severe lymphangitis, and an erysipelatous-like condition of the leg. During and after various *intestinal infections*—as, for instance, typhoid and paratyphoid—occasionally a suppurative inflammation of some lymphatic glands—sometimes the inguinal glands—occurs. In such cases the history of the case—the fact that the bubo comes, as a rule, to suppuration—and the bacteriological examination of the gland-juice, which in true climatic bubo is sterile, will clear the diagnosis.

Prognosis.—The prognosis is favourable, though in some cases the affection may last for several months. A relapse may occasionally occur shortly after the first attack is over, sometimes on the side previously affected, sometimes on the other side.

Treatment.—The treatment is merely symptomatic, consisting of complete rest, application of lead lotion on the affected region, or an ichthyol and belladonna ointment, together with the administration of a mild aperient, and, if there is much pain, a hot fomentation locally together with small doses of opium by the mouth. In the rare cases, where signs of suppuration are noticeable, incision of the glands is necessary, using the ordinary aseptic precautions. In protracted cases complete surgical removal is the best treatment. When the glands remain enlarged after the acute stage has passed off, local applications of tincture of iodine, iodine valsol, or an ointment composed of 30 grains each of lead iodide and potassium iodide to 1 ounce of vaseline may be of benefit. X-ray treatment has been recommended by G. Rost.

VOLVULOSIS.

Definition.—Volvulosis is a disease caused by *Onchocerca volvulus* Leuckart, 1893, and characterized by the formation of fibrous, cutaneous, or subcutaneous tumours.

History.—As already mentioned on p. 649, these tumours were discovered by a German medical missionary to contain worms, which were described by Leuckart in 1893, and subsequently the disease and its causative worm were studied by Labadie-Lagrave and Deguy in 1899, Prout in 1901, Brumpt in 1904, Ziemann and Védy in 1907, and Fülleborn in 1908, the last paper being a most valuable contribution to our knowledge of the subject.

Climatology.—The disease is found in Africa, at Sierra Leone, on the Gold Coast, and in Dahomey, Cameroons, and the north-east of the Congo, where it is variously stated to affect from 1 per cent. to 10 per cent. of the population, being distributed along the banks of rivers. Brumpt found it along the Welle, Cooke in Uganda, and Parsons in Northern Nigeria.

Ætiology.—The disease is caused by *Onchocerca volvulus* Leuckart, 1893, but the method by which this worm is introduced into the human body is quite unknown, as is also its life-cycle outside human beings.* Brumpt has, however, suggested that it will probably be found in a tsetse-fly, because of its riverine distribution and the fact that microfilariæ have been found in the peripheral circulation by Fülleborn, Rodenwalt, and others.

Pathology.—The adult worms lie in lymphatics, the anterior end of the female being in close approximation to the posterior end of the male, because the apertures of the genital apparatus lie in these positions. By some means—possibly by the presence of the *Microfilaria*, or possibly by toxic waste-products—these worms irritate the lymphatics, causing lymphangitis and perilymphangitis. These inflammatory processes eventually lead to the formation of a fibrous capsule around the worms, which then lie in a portion of a vessel cut off (?) from the rest of the lymphatic system, and which forms a fibrous subcutaneous nodule containing male and female worms and *Microfilariæ*.

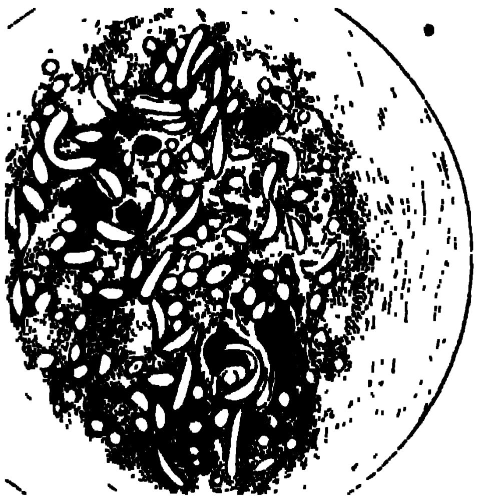

FIG. OUR CONTAINING *Onchocerca volvulus* L

(After Fülleborn.)

On opening one of these tumours it is seen to consist of a capsule of fibrous connective tissue, beneath which is some soft caseous material composed of endothelial cells, granular débris, and *Microfilariæ*, and to enclose a central space containing a greenish, semi-purulent fluid. The worms, which are usually cut across in several places when opening the tumour, lie partly in this central cavity and partly in narrow twisted tunnels, which ramify through the walls of the fibrous capsule, giving it a network-like appearance. Sometimes the central cavity is not obvious, and only the network of tunnels is seen ramifying through the connective tissue.

Symptomatology.—The disease, as a rule, begins insidiously with malaise, weakness, vague pains in various regions of the body, and irregular fever, but it is said that at times attacks of lymphangitis may be noticed. In due course a tumour is discovered in the sub-occipital region, the elbow, axilla, side of the chest, iliac region, gluteal region, or popliteal space. These tumours vary in size from a pea to that of an egg, and lie in the skin or subcutaneous tissue, in which they are freely movable. They may be elastic if they contain fluid, or firm if composed mainly of fibrous tissue. They usually remain quiescent for years, and but seldom ulcerate.

Bernard and Ouzilleau believe that *Onchocerca volvulus* may also give rise to true elephantiasis in certain parts of Africa.

Diagnosis.—The presence of an elastic tumour somewhat resembling a lipoma, or of a firm fibrous tumour in any part of the body of a person who has resided in the endemic region, should arouse suspicions as to the presence of *Onchocerca volvulus*.

When the nodules are in the proximity of articulations the condition may closely resemble the 'juxta-articular nodules' (see p. 2260). The microscopical examination of the contents of the nodules obtained by tapping with a syringe or by excision will clear the diagnosis.

Prognosis.—These little tumours are not in any way dangerous to the life or health of the patient.

Treatment.—Removal by incision and enucleation is quite easy, and devoid of danger.

Prophylaxis.—As the life-cycle of the parasite is unknown, nothing can be said as to prophylaxis.

CHAPTER LXXXVIII

DISEASES OF CONNECTIVE TISSUES, MUSCLES, BONES AND JOINTS

General remarks—Somatic tæniasis—Subcutaneous filariases—Dracontiasis—Dermo-conjunctival filariasis—Lōiasis—Calabar swellings—Dubini's filariasis—Myositis purulenta tropica—Goundou—Boomerang bones—Pes gigas—Endemic enlargement of the os calcis—References.

GENERAL REMARKS.

THE diseases of the connective tissues which concern us are mostly parasitic, being caused by the cysticerci of tape-worms, but round worms are also commonly met with, especially the guinea-worm.

With regard to muscles, a disease which must be mentioned is *trichiniasis*, which is said to be far from rare in Northern India. *Necrosis, caries, and tumours* of bone are not uncommon, but *rheumatoid arthritis* is rare, and *tubercular disease*, at present, is very rare. *Gonorrhœal* and *post-dysenteric arthritis* are met with, and *filarial synovitis* of the knee-joint has been described by Maitland. *Gout* is rare, but we have seen a typical case in a native who had never left Ceylon

A peculiar condition called 'trench foot' has been met with in war zones in the winter, and is therefore not a tropical disease. It is a painful congestion of the foot, sometimes leading to gangrene, and associated with the presence of spirochætes and other organisms in the bullæ (see p. 2110).

DISEASES OF CONNECTIVE TISSUES.

SOMATIC TÆNIASIS.

By somatic tæniasis is meant the invasion of the body by the cysticercus of cestode worms. The subject is, therefore, divisible into—(*a*) *Cysticercosis*, or infection with the larvæ of *Tænia solium*, which occurs now and again in the connective tissue of muscles, fasciæ, and in the brain; (*b*) *Echinococcosis*, which is the infection of the body with the hydatids of *Echinococcus granulosus*, and of which we have only met with one example in the tropics, and even then it was imported; but, judging by Begbie's observations, it would appear as though the disease was endemic in Ceylon; (*c*) *Sparganosis*, which is the invasion of the body by *Sparganum mansoni*, *S. baxteri*, or *S. prolifer*, all of which have been sufficiently described in Chapter XXV., p. 596.

THE SUBCUTANEOUS FILARIASES.

Definition.—The subcutaneous filariases are infestations of the subcutaneous tissue by the adult worms of species belonging to the Filariidæ other than *Filaria bancrofti* Cobbold, 1877.

Remarks.—The form of filariasis caused by *F. bancrofti* is detailed in Chapter LXVI., and now we consider those in which the adult worm lives in the subcutaneous tissue. The varieties of this form of filariasis are dracontiasis, or guinea-worm infection, and dermo-conjunctival filariasis.

DRACONTIASIS.

Synonyms.—Dracunculosis, Turkish disease.

Definition.—Dracontiasis is the infection of man with *Dracunculus medinensis* (Linnæus, 1758), the guinea-worm (p. 651).

History.—The disease has been known from very remote periods, and it is probable that the fiery serpents which attacked the Israelites in the desert were guinea-worms, and that the serpent on the stick was an illustration of the method of extraction advised.

Plutarch (A.D. 50-117) gave an account of the disease as seen on the shores of the Red Sea, while Galen (A.D. 131-210), who never saw a case, called the disease 'dracontiasis.' Oribasius also mentions it and the worm, and Aëtius, quoting from Leonides, says that it occurs in the legs and arms of people in Ethiopia and India. Paul of Ægina stated that in India and in the upper part of Egypt there was a class of worms called 'dracunculi,' formed in the muscular parts of the body such as the arms, thighs, and legs, and under the skin in the sides of children, which moved, and after a time the skin opened and the head came out. He advises that this be fixed with a piece of lead, the part placed in hot water, and the worm gently pulled, when it will come out by degrees; but if during this process it breaks, there will be much pain. Pollux calls it a corrupted nerve, and Actuarius writes about its presence in Egypt. Avicenna calls it *Vena medina*, after Medina, where it was common. He notes the bleb which it makes in the skin, and its protrusion after the bleb bursts. He recommends ligatures above the worm and baths to make it come out. Haly Abbas says that it occurs in India, Egypt, Ethiopia, and Libya, while Avenzoar notes that it is most common in negroes. Albucasis, Rhases, Bertapalia, and Guy de Cauliac, all mentioned the disease, and the last named calls the worm *Vena civilis vel medina*, while Audry considers it to be an animal. Other writers on this subject are João Rodrigues de Castell Branco (1511-1568), Linscholeri (1599), and De la Motte Lambert (1666). In 1674 Velsch wrote a book on the subject and saw guinea-worms everywhere.

The scientific study of the disease and its parasite dates from the work of Fedschenko in Central Asia, in 1870, when he discovered its development in the cyclops, the integument of which he believed the young worms pierced.

Fedschenko's observations were confirmed by Manson, Blanchard, and by Wenyon working in the Sudan. The cyclops swallow these embryo worms as food, and Indian observers have noted that the worms are at first coiled up in the stomach, but later they pierce the wall of this organ and escape into the body cavity, and may kill the cyclops. In the body cavity they shed their cuticle about the seventh day and undergo developmental changes, and will remain alive in this cavity for some fifty-three days.

In 1907 Leiper proved that the infection of man was *per os*, the cyclops being swallowed in water. In the stomach the crustacean is killed, but the worm escapes through the digested integument of the cyclops, bores its way through the wall of the vertebrate stomach, and in about eight to twelve months becomes the adult female, measuring some 30 inches, but during this process she moves about and finally produces the blister, where water can be touched, and so gets her young into water.

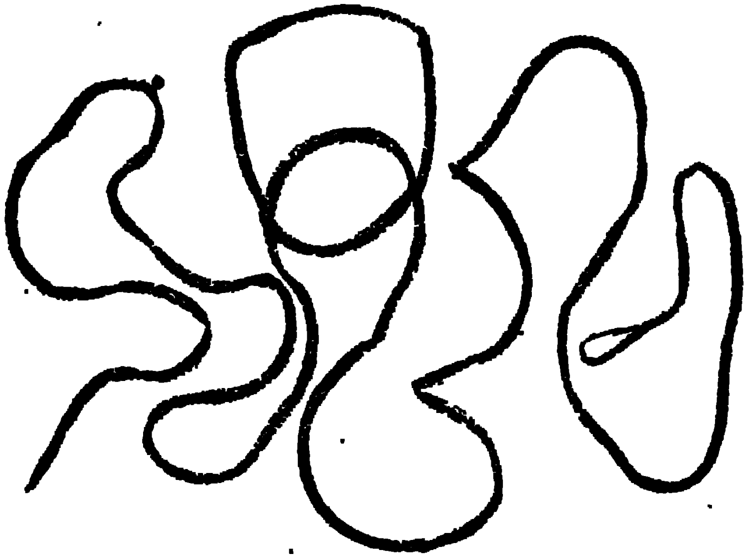

FIG. 788A.—GUINEA WORM SOMEWHAT SHRIVELLED FROM ACTION OF PRESERVING FLUIDS. (HALF NATURAL SIZE.)

In 1913 Turkhud extended our knowledge considerably, and has shown that a man who drank water containing infected cyclops on April 5, 1913, showed the worm on March 18, 1914—*i.e.*, 348 days later. He also demonstrated that the worm would not develop in *Macacus sinicus*.

Whether there is more than one kind of guinea-worm is not known, but Scheube says that Cholokowski has described an unclassified filaria, several inches in length, which causes ulceration of the fingers, and even gangrene, in Tiver, in Russia, which may or may not be the same worm.

Climatology.—Dracontiasis is a disease of the tropics, especially of tropical Africa, and particularly of the West Coast. It is also known in Asia Minor, Persia, and India. Although coolies infected with the worm frequently pass from India to Ceylon, we have no evidence that the latter island has so far become infected. It is also known in the Fiji Islands. It was introduced into America by the negro slaves, and has become endemic in British Guiana and Brazil.

Ætiology.—The causation of the disease is *Dracunculus medinensis* Linnæus, 1758, taken into the body by drinking water containing infected cyclops, which are most abundant during the dry season, and which mostly live near the bottom of wells and collections of water.

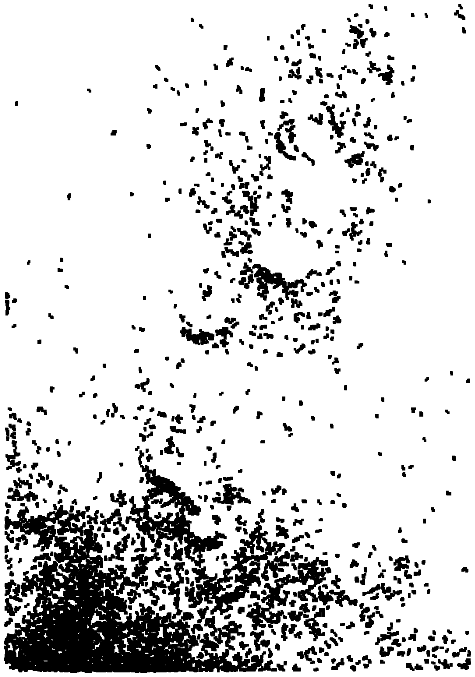

FIG. 789. GUINEA WORM UNDER THE SKIN.

(From a photograph by Christopherson.)

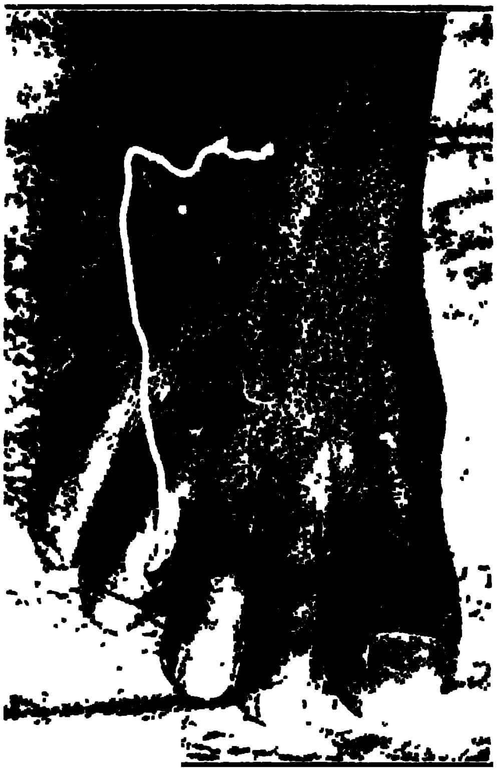

FIG. 790. GUINEA-WORM IN PROCESS OF EXTRACTION.

(From a photograph by Christopherson.)

Pathology.—On entering the stomach the cyclops is killed by the action of the acid of the gastric juice but the *Dracunculus* is stimulated, and, dashing about energetically, effects its escape from the cyclops, and, piercing the walls of the stomach, enters the connective tissue of the mesentery and becomes an adult.

After a time the fully-developed female begins to travel in search of a means of depositing the larvæ in water, and therefore usually wanders into the leg, and forming first a vesicle and then an ulcer in the skin, discharges the larvæ.

Symptomatology.—The worm as a rule produces no symptoms until a little vesicle appears on the skin, or the outline of the worm is noticed under the skin, but urticarial eruptions have been observed by several authors and ourselves. The little vesicle bursts, leaving a round hollow, out of which exudes a clear fluid full of larvæ, and at the bottom of which lies the vaginal orifice of the worm. After discharging a certain amount of fluid, the anterior end of the worm extrudes through the skin opening, and is either twisted on a stick or fixed in position by a piece of string by the native patient. It is not advisable to pull vigorously on the protruded piece of worm, as it is liable to break, and if this happens a serious inflammation of the affected area may result. The wound usually quickly heals after the worm has finally been extracted. The usual site for it to appear is about the feet or legs, more rarely the hands or arms, and still more rarely the head or trunk.

But all cases are not so simple, and aching or dragging sensations, sometimes accompanied by rigors and fever, may occur. Rarely it enters a knee-joint and causes synovitis or arthritis. Usually there is only one worm, but there may be more.

Blood.—Dudgeon and Child have investigated the blood in this disease, and find a marked eosinophilia. The average differential count was as follows: Polymorphonuclears, 63·6 per cent.; lymphocytes, 18·4 per cent.; large lymphocytes, 2·8 per cent.; mononuclears, 1·6 per cent., eosinophiles, 13 per cent.

Diagnosis and Prognosis.—There is no difficulty in the diagnosis, and the prognosis is good.

The X rays are useful in detecting encysted calcified worms, which may cause obscure purulent conditions

Treatment.—It is a good plan to massage the area above the vesicle, and try with a little patience to get the worm out whole, or, if it is visible under the skin, to make an incision and remove it. Natives extract the worm by twisting the protruding portion on a stick, every day giving a turn or two. A better plan is to douche frequently with water the part occupied by the worm until she gets emptied of all the embryos, which generally takes place in from two to three weeks. When all the embryos have been exuded, the worm is either absorbed or tends to emerge, and, no longer resisting extraction, can be easily removed. It has been advised (Emily) to inject a 1 per 1,000 solution of perchloride of mercury into the swelling caused by the worm. But this is very painful, and does not appear to be very successful. Some authors have advised the injection of 10 to 15 minims of a 2 per cent. solution of cocaine into the protruding portion of the worm.

Prophylaxis.—The prophylaxis is very simple—viz., the drinking of only boiled and filtered water. Another simple method suggested by Leiper is to pass steam into the wells.

THE DERMO-CONJUNCTIVAL FILARIASES.

These are Löiasis, Calabar swellings, and Dubini's filariasis.

LÖIASIS.

Definition.—Löiasis is a subcutaneous and subconjunctival filariasis caused by *Loa loa* (Guiyot, 1778).

Remarks.—*Loa loa,* which is carried by a species of Chrysops, as discovered by Leiper, has frequently been noticed in the ocular and palpebral conjunctivæ crossing the bridge of the nose, in the skin over the sterno-mastoid muscle, or that of the scalp, the fingers, the penis, etc., and much more rarely in the anterior chamber of the eye, though accounts of its presence in the vitreous humour require confirmation. For description of the worm see p. 645.

Climatology.—The geographical distribution of the worm is confined to the West Coast of Africa from Sierra Leone to Benguela, but is most particularly Old Calabar, the Cameroons, and the Ogomé River. It penetrates some six hundred miles or more into the interior of Africa.

Symptomatology.—In our experience it usually causes but little disturbance, but at times, when in the conjunctiva, it is associated with piercing and lancinating pains, uncertain vision, and swelling of the eyelids. It is probably the cause of the Calabar swellings mentioned below.

Treatment.—It can be removed by an incision and careful traction. Hot fomentations, as noted by Elliott, cause the worm to come to the surface.

CALABAR SWELLINGS.

Synonyms.—Kamerungeschwülste, Tropical swellings, Ndi-töt = swelling (Calabar).

Definition.—Calabar swellings are smooth, temporary, slightly raised tumours on the head, arms, hands, ankles, and feet, probably caused by the presence of *Loa loa* (Guiyot, 1778), and possibly other species of filaria or allied genera in the subcutaneous tissue.

History.—For many years it has been known that peculiar swellings occurred in the people living in Old Calabar, and in due course accounts appeared in works of travels in West Africa, but it was not till 1895 that Argyll Robertson described them as a distinct disease, using their popular nomenclature. In subsequent years he published several accounts of his cases. In 1898 Plehn drew attention to the complaint, and in 1899 Thompstone published an account of a case, while Habershon and Kerr in 1904, Wurtz and Clerc and Stephens in 1905, and Ward in 1906, have all added to the literature of the subject.

The paper by Ward is, however, of especial interest, as it deals fully with the history of the disease.

Climatology.—The disease is only known on the West Coast of Africa, particularly in the regions of Southern Nigeria and the Cameroons. We have seen, though rarely, a similar condition in Ceylon, where the existence of *Loa loa* has not been reported.

Ætiology and Pathology.—There is a consensus of opinion that in some way these swellings are caused by *Loa loa* Cobbold, 1864, but this has never been definitely proved.

The way in which the worm induces these peculiar lumps is a matter of conjecture, Argyll Robertson assigning them merely to the movements of the parasite. But this cannot be so, otherwise the swellings would occur as they cross the bridge of the nose, which they can do without any such disturbance.

The next theory is that the parasite irritates the skin, causing the patient to rub the affected area, which in this way becomes mechanically inflamed. This theory was originally propounded by Manson, who has relinquished it in favour of another and better explanation.

Two other theories suggest that the parasite, by irritating the nerve endings, either directly or by reflex action, causes the swelling; but this does not appear likely, as they ought to occur wherever the worm travels. Manson in 1903 suggested that they might be brought about by the expulsion of the microfilariæ from the uterus of the parent worm, and this appears not unlikely, and would explain their evanescent character.

Ward is not satisfied with Manson's theory, and suggests that they may be due to the expulsion of waste products from the worm.

Age, sex, and employment have no influence in the causation of the complaint.

Symptomatology.—Sometimes without prodromal symptoms, or at times after some nausea and headache, swellings appear on the head, face, arms, wrists, hands, fingers, ankles, or toes, less commonly on other parts of the body. The reason of this distribution, according to some authors, is believed to be the small amount of connective tissue in those regions. The swellings are smooth, firm, slightly elevated areas, generally about the size of half a goose's egg (5 to 8 centimetres), often painless, though this is not invariable. There is either absence of or only very slight pruritus. They are hot, and do not pit much on pressure. They appear quickly, last for two or three days, and disappear gradually or rapidly, and are always associated with an intense eosinophilia. In many cases only one swelling appears at a time.

Stephens gives the differential count of his case as—Polymorphonuclears, 26 per cent.; lymphocytes, 23 per cent.; mononuclears, 1 per cent.; eosinophiles, 50 per cent.

Diagnosis.—There is no difficulty in recognizing these fugitive swellings in persons who have resided in the endemic region. The presence of extremely well-marked eosinophilia may help in the diagnosis.

Prognosis.—They have never been known to cause serious symptoms, but may recur for many years after the patient has left the tropics.

Treatment.—This is unsatisfactory, but cool applications such as diluted liquor plumbi (5 per cent.) may be made to the swellings, and an ichthyol ointment or lotion applied.

Prophylaxis.—As our knowledge of the life-cycle of *Loa loa* is very incomplete, it is not possible to lay down rules for the prophylaxis.

DUBINI'S FILARIASIS.

Definition.—Dubini's filariasis is a dermo-conjunctival filariasis caused by *Filaria conjunctivæ* Addario, 1885.

History.—The immature female worm was originally discovered by Dubini in the subconjunctival tissue of a man in Milan, and is possibly the same as that described as *Agamofilaria oculi humani* von Nordmann, 1832, and as *Agamofilaria palpebralis* Pace, 1867, *nec* Wilson, 1844. In 1880 Babès found another immature female worm in a calcified nodule in the gastro-splenic omentum of a woman in Budapest. He named it *Filaria peritonei hominis*. In 1885 Addario named a female worm extracted by Vadela from the conjunctiva *F. conjunctivæ*. Vadela's case was a woman from Catania in Sicily. In 1887 Grassi gave a full description of the female worm, calling it *F. inermis*, because of the absence of papillæ on the head. In 1906 Alessandrini found it in an abscess in subcutaneous tissue of the arm; and in 1918 Graham Forbes met with two cases in the subcutaneous tissue of the forearm and of the nose, and was the first to describe the adult male.

It is the same as the worm called *Filaria papillosa* Rivolta, found in the eye of an ass at Pisa, and also *F. apapillocephala* Condorelli-Francaviglia.

Climatology.—The worm is found in Italy, Sicily, Hungary, Macedonia, and Roumania. It is a parasite of the horse and ass, and but rarely of man.

Ætiology.—It has been suggested that the worm is introduced by the bites of *Chrysops excutiens*.

Morbid Anatomy.—The nodule containing the worm consists of fibrous connective tissue with round-celled infiltration and traversed by lymph spaces.

Pathology.—It is thought that the worm enters a lymphatic canal, which becomes cut off and is surrounded by an inflammatory reaction. No microfilariæ can be found in the blood or in the nodules.

Symptomatology.—Marks of a bite have been seen in only one case. Usually it is a small tumour in some area of the body which is the first sign to attract attention.

The differential blood count is as follows:—

	Per Cent
Polymorphonuclear leucocytes	47·0
Mononuclear leucocytes ..	10·5
Small lymphocytes	38·0
Eosinophile leucocytes ..	3·5
Basophile leucocytes	1·0

As time progresses the little lump may become hot and swollen, but not painful. After these inflammatory symptoms have lasted for some three days they subside, only, however, to recur again in about ten to fourteen days, and this cycle recurs and recurs. Sometimes an abscess forms in which the worm or its remains can be found.

Treatment.—The correct treatment is to excise the nodule.

Prophylaxis.—Nothing can be said under this heading, as the method of infection is unknown.

DISEASES OF MUSCLES.

MYOSITIS PURULENTA TROPICA.

Synonyms.—Muma fever (Samoa), Bungpagga (Northern Gold Coast).

History.—This condition has been observed in various parts of the tropics, including the northern territories of the Gold Coast, by several observers, among whom Van Polak, Ziemann, Külz, may be mentioned. The last-named author has given a good general account of the malady.

Climatology.—The disease is found in tropical Africa and Samoa.

Ætiology.—Some authorities suggest that it is due to a *Filaria*

Symptomatology.—The patient complains of rheumatoid pains in the limbs associated with fever of a remittent or intermittent type. Abscesses form in the muscles in various parts of the body.

Treatment.—This is surgical, the abscesses being evacuated.

DISEASES OF BONES.

GOUNDOU.

Synonyms.—Anákhré big-nose; Henpuye = dog-nose.

Definition.—Goundou is a disease of unknown causation, characterized by a bony swelling, usually bilaterally symmetrical, situated on either side of the nose.

History.—The disease was first described by Macalister in 1882, under the term of 'the horned men of Africa.' Lamprey in 1887 also referred to the disease under a similar term, and Strachan drew attention to it in a West Indian child in 1894. Maclaud in 1895 described the disease which he saw on the Niger under the terms 'goundou' or 'anákhré.' In 1900 Chalmers gave an account of the disease as seen on the Gold Coast, and Renner as seen in Sierra Leone. Later Braddon recorded a case in Malaya, and others found the disease in Sumatra and in China. Friedrichsen gave an excellent description of it as seen in East Africa, and Nell gave an account of his cases on the Gold Coast, while Cantlie records a case of unilateral goundou in a European. Lastly, Roques and Bouffard, and more recently Roubaud, Blin, Marchoux, and Mesnil and Léger, have recorded cases in monkeys—*Papio anubis*, *Cercopithecus* sp. ?, and *Callitrichus*.

The first three observers found that the condition affected many bones of the skeleton, besides the nasal bones. Letulle has noticed a somewhat similar condition in the skull of an ancient Inca found in a Peru necropolis.

Climatology.—The disease is most commonly met with in West Africa, but has been reported from East Africa, Malaya, Sumatra, South China, and the West Indies. It usually affects native races, but has been reported in one European. Usually it begins in the first two decades of life.

Ætiology.—This is unknown, though the association with yaws gave rise to the suspicion that this was the ætiological factor. Cantlie's European, however, had not suffered from yaws, and monkeys do not suffer spontaneously from yaws.

Occasionally in yaws patients a bilateral or unilateral swelling of the nose is present (pseudo-goundou of Brumpt), but it quickly disappears along with the other symptoms of yaws under treatment with potassium iodide or salvarsan, which has no effect on true goundou.

Other theories have been that it was a racial trait, or that it was due to a larva of a fly, but these are certainly not correct. As far as we know, it is never congenital. Braddon thinks that it is a disease *sui generis*, and in our opinion is probably right.

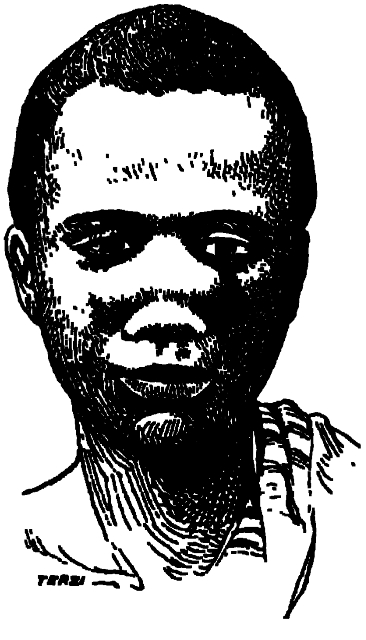

FIG. 791.—GOUNDOU IN A NATIVE OF THE GOLD COAST.

Pathology.- Whatever the cause may be, there seems no reasonable doubt that the infection begins in the nose; for although we were unable to find any abnormality in the nose of the cases we have seen, still, there was always a history of some obstruction, pain in the nose, and often of a bloody discharge. Moreover, Friedrichsen describes a swollen condition of nasal mucosa with almost polypoid excrescences. Léger has noted microscopically a proliferation of embryonal cellular elements derived from the bone-marrow infiltrating the bone-tissue. This is followed later by a true process of cicatrization or osteosclerosis. If this is correct, it is quite easy to understand that the vessels passing from the nose through the *sutura notha*, in the nasal process of the superior maxilla, can carry that infection to the periosteum, which, being irritated, proceeds to an excessive formation of bone in the area of that suture. This results in the formation of a bony swelling, composed on the outside of a thin shell of compact bone, underneath which is spongy, bony substance continuous with that of the bone from which it is arising. The *sutura notha* is, of course, found in all human skulls, and is not peculiar to the negro race.

The bony growths are attached to the nasal bone, the nasal process of the superior maxilla, and at times to the maxilla itself. The periosteum strips off readily, but usually shows no signs of recent inflammation.

Symptomatology.—Generally the disease begins with pain in the nose, or headache, which may be severe, and a bloody nasal discharge, which may continue for some six to eight months. When this is disappearing, it is noticed that there is a swelling, usually symmetrically placed on either side of the nose, in the region of the nasal bone and nasal process of the superior maxilla. Slowly and steadily these lumps increase in size, interfering with vision (it is said at times destroying the eyes), and giving rise to a hideous deformity rather like a *Cynocephalus* monkey, and hence called 'dog-nose.' When fairly well developed, an oval, bony swelling, with its long axis directed downwards and outwards, is seen symmetrically placed on each side of the nose; the skin over the tumour is never affected, being freely movable; and usually, when examined, the nasal mucosa is found to be normal, and the nasal ducts are patent, but there may be swelling and even polypoid-like excrescences. Occasionally a similar growth may invade the nose, partially blocking the nasal cavity. The growth, however, may stop at any stage of it's development, and proceed no farther. Some authors describe a curvature of the tibiæ as being associated with the disease.

Varieties.—Instead of being bilaterally symmetrical, the bony lump may develop only on one side of the nose. Orpen has described, in addition to the two usual tumours, a third in the malar region.

Diagnosis.—The symmetrical bony swellings at the root of the nose are characteristic, but must be distinguished from Brumpt's pseudo-goundou of framboesial origin by the history and by the inutility of salvarsan and potassium iodide.

Treatment.—Medical treatment is useless, and removal is not merely easy, but most effective, as the disease is known not to have returned some six or seven years after the operation.

Prophylaxis.—As the causation is doubtful, nothing can be said under this heading.

BOOMERANG BONES.

Synonym.—Boomerang leg.

Definition.—A disease of the long bones commencing gradually, and associated with pain, tenderness, and longitudinal bowing of the bones, which remain permanently deformed after the acute symptoms have disappeared. Several conditions are apparently covered by this term.

History.—The disease was first described in the second edition (1913) of this work from information received from Ernest Black. He described it as seen in the aboriginal natives of the north of Western Australia and the Torres Straits Islands. In 1915 Breinl and Priestley gave an account of the disease as seen in Northern Queensland and Western British New Guinea. In 1918 Christopherson described a similar condition as seen in the Anglo-Egyptian Sudan.

Climatology.—The disease is known in the northern portion of Australia, the islands of the Torres Straits, in the Sudan, in British New Guinea.

Ætiology.—This is unknown. It is not syphilitic, tubercular, osteomalacic, nor due to rickets. Black considers the condition to be due to hypofunction of the thymus gland. A clinically similar condition is undoubtedly a late manifestation of yaws.

Pathology.—The disease is believed to begin as a rarefying osteitis which causes softening and permits the bending of the bones. This is followed by a condensing osteitis and formation of periosteal bone fixing the deformities.

Morbid Anatomy.—The bending in the tibia takes place at the junction of the upper with the middle thirds. The bone is heavy, and compact in the centre and freer at the ends. The narrow cavity is almost filled in with compact bone.

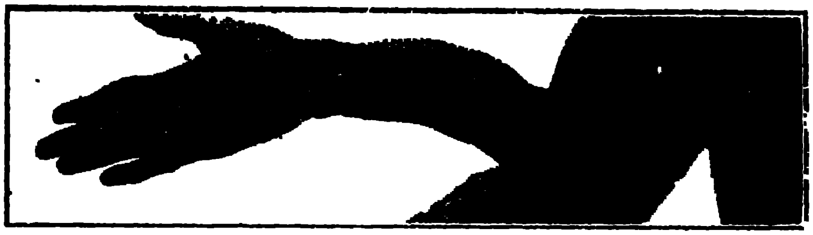

FIG. 792.—BOOMERANG DISEASE.
(From a photograph by Christopherson.)

Symptomatology.—The onset is gradual in young natives during the period of growth. There are pains in the shins, severe enough to prevent walking, and the skin over these bones is tender. The subcutaneous tissues become inflamed, and there is some febrile disturbance. After the acute symptoms and pain have subsided the children start to walk, and the bones bend forward gradually, thus giving rise to the characteristic deformity, which becomes permanently fixed.

Other bones may become similarly affected.

Treatment.—This is nil at present.

Prophylaxis.—Unknown.

PES GIGAS.

Synonym.—Congenital partial hypertrophy of the foot.

Definition.—Hypertrophy and fusion of the inner metatarsal bones, with club formation of the ends of the toes.

History.—Cousland, in the *Journal of Tropical Medicine* for January, 1900, gave an illustration of the disease as seen in a young Chinaman. Raynaud saw the disease in a Kabyle and Legrand in a European.

Symptomatology.—The condition is congenital, and may be studied by the X rays, when it will be seen that the three inner metatarsal bones are hypertrophied, and the second and third united, while the terminations of the toes are club-like. In Cousland's case there was marked hypertrophy of the calf muscles.

Treatment.—It has not been treated so far as we know.

ENDEMIC ENLARGEMENT OF THE OS CALCIS.

Definition.—Endemic enlargement of the os calcis is a disease of unknown causation, characterized by fever, pain, and tenderness over, and subsequently enlargement of, the os calcis.

History and Climatology.—This disease was first described by MacLean in 1904 in Fantis and Krooboys in the Gold Coast Colony, and subsequently in 1905 by Maxwell in natives of Formosa.

Ætiology.—The ætiology and pathology are obscure, but in some way it is connected with the wet season, as attacks and recurrences take place then.

Symptomatology.—The disease begins suddenly with fever, great tenderness over the os calcis, with local pains so severe as to prevent sleeping and walking. In three to seven days the outer surface of the bone begins to increase in size, and continues to do so for some two weeks, during which time the pain lessens and the temperature falls to normal.

In about a month the swelling reaches its maximum size, at which it may remain for about one to two months, during which time the pain is moderate and walking is possible. After this the bone diminishes to about half the maximum size, but sometimes considerable enlargement persists. Usually the disease is bilaterally symmetrical, but it may occur on one side only. It affects the outer surface as a rule, but may also attack the posterior third of the bone.

Rarely it attacks other tarsal bones, but has never been reported as affecting a joint. Yearly recurrences during the wet season are common.

Treatment.—Medical treatment is useless, but relief is given by cutting down on to the affected area and trephining a hole into the bone.

Prophylaxis.—Concerning this nothing is known.

CHAPTER LXXXIX

DISEASES OF THE NERVOUS SYSTEM

General remarks—Endemic paralytic vertigo—Lâtah—Banga—Schamanismus—Âmok—Tropical neurasthenia—Endemic peripheral neuritis—Erythromelalgia tropica—Desert hallucinations—Emotional excitement—Delusions—Auto-suggestion—References.

GENERAL REMARKS.

The nerve diseases of the tropics include many general diseases already dealt with e.g., pellagra, leprosy, beri-beri, etc. But apart from these conditions, *meningitis, cerebral tumours, cerebral hæmorrhages, spastic paralysis, alcoholic neuritis*, and, more rarely, *arsenical neuritis*, are all well known. *Locomotor ataxia* and *general paralysis*—the so-called parasyphilitic affections are rare, though syphilis is rampant. The *cerebral tumours* which we have most commonly met with are endotheliomata and tubercular or syphilitic lesions. *Hysteria* is common among the better-class natives, especially among the young women educated according to Western ideas.

As regards insanity, *mania* and *melancholia* are the most usual; but *dementia, idiocy*, and *epileptic insanity* are not uncommon. According to Spence, the burden of lunacy in Ceylon is light as compared with England, Scotland, or Ireland, and it is possible that this applies not merely to Ceylon, but to other countries. But apart from these diseases, there are some curious nerve or mind affections which must be considered at greater length.

Sexual perversions are not uncommonly met with in native races.

Homicidal tendencies are generally due to alcoholism, or to long brooding over real or fancied injuries. *Suicide* is not rare, and may be approved by local custom.

Tropical 'kohler' has already been mentioned (p. 76), but tropical neurasthenia, endemic vertigo, and other conditions must be briefly touched upon.

War Zone Neuroses.—The recent war has greatly improved the general knowledge of neurotic conditions. It has been shown that congenital nervous conditions, concussion, chronic alcoholism, and sexual troubles are predisposing causes; while *exhaustion* due to mental or physical strain, toxæmia, insufficient food, pain, excessive heat, or *emotion* due to horrors or constant pain, *traumatism*, particularly concussion, are the exciting causes. The neuroses produced by the above-mentioned causes, according to Hurst, are neurasthenia, soldier's heart, stupor and amnesia, psychasthenia, hysteria, exaggerated defensive reflexes, hyperthyroidism, hyperadrenalism, and shell shock.

The pathology of some of these conditions has been carefully investigated by Mott. Many persons suffering from shell shock have been permitted to go on duty to the tropics, with often unpleasant mental results. These persons are especially liable to be influenced by the sun's rays.

ENDEMIC PARALYTIC VERTIGO.

Synonyms.—Vertige Paralysante, Vertige Ptosique Gerlier's disease, Kubisagari, Tourniquet.

Definition. Endemic paralytic vertigo is characterized by eye symptoms, such as ptosis, dimness of vision, and by paralysis of the neck and extremities.

History.—The disease was first described, in 1884, by Gerlier in Ferney, in Switzerland, in 1886, and by Miura, in 1894, in Japan.

Climatology. It is known in France, Switzerland, and Japan, where it is found in the northern provinces and in the island of Shikoku. It begins in spring, attains its greatest numbers in summer, and ends in autumn.

Ætiology.—The ætiology is entirely unknown, and hence there are many theories, which suggest alcohol, poisoned bread and lentils, and latent malaria; but the one which is favoured by both Gerlier and Miura is the association of the disease with stables. Gerlier says that in the valley of the Lake of Geneva it is not unusual for people to sleep in the stables; and Miura says that in the regions affected in Japan it is usual to have the house so arranged that a part is used as a stable, while the remainder is occupied by the family.

Further, it is associated with warm weather. Miura gives as exciting causes bodily exertion while hungry or after a full meal, writing, reading, steady attention to anything, uniform movements, or mixing with crowds; while the attacks are diminished by rest and change. Couchoud and Shionoya found a Gram-negative coccus in the cerebro-spinal fluid. This they grew artificially, and stated that they reproduced the disease by injecting this into cats.

Pathology.—This is quite unknown.

Symptomatology.—An attack begins with a blurring of objects, everything appearing as if in a fog, together with ptosis, and, less frequently, a diplopia due to paralysis of the internal rectus, with sometimes photophobia, disturbances of colour vision, and hyperæmia of the optic disc. Then follow disturbances of speech and loss of power in mastication, and, in bad cases, of deglutition. At the same time paralysis of the muscles of the back of the neck, the back, and the extremities are observed. The head falls forward, and is only raised with difficulty; hence the name of the disease, 'kubisagari,' which means 'he who hangs his head.' If the muscles of the back are paralyzed, there may be difficulty in raising the body from a stooping posture. Weakness in the hands, arms, and legs is often observed, and is first noticed in the muscles connected with symmetrical repeated movements. An attack lasts from ten to fifteen minutes, and varies in severity, in mild cases there being only ptosis and dimness of vision. Between the attacks the patient is perfectly well in every respect. After severe attacks there may be a little ptosis, or weakness of the muscles of the back, neck, hands, or legs, and increased reflexes.

Diagnosis.—The characteristic symptoms are: Ptosis and the falling forward of the head and neck. These symptoms differentiate it from the other forms of vertigo.

Prognosis.—The disease is never fatal, though it may last for many years.

Treatment.—The first requirement is removal from the endemic area and from living in close proximity to stables. Medicines are not of much use, but a combination of potassium iodide and arsenic is recommended.

LÀTAH.

Synonyms. Echomatism Mimicismus, Sakitlatah, Jumping, Bahtschi, Myriakit, Menatscheme.

Definition. Lâtah is a mental condition in which suggestion is at once followed by uncontrollable action in the form of echolalia or echokinesia, of which the mind is usually, but not always, conscious.

History.—The convulsive tics have been carefully studied in Europe by Charcot, Gilles de la Tourette, and Guinon, but the allied condition 'lâtah' found in Malaysia, as well as similar conditions found in other parts of the world, have as yet not been fully investigated. Thanks to the labours of O'Brien in 1883, Gilmour in 1892, Van Brero in 1895, Ellis in 1897, Gerrard in 1904, Manson in 1907, Fletcher in 1908, Plan in 1911, and Abraham in 1912, a fair amount of definite information with regard to lâtah is available.

Climatology.—Lâtah is found principally in the Malay Peninsula, Java, Sumatra, and is also known in Siam, in Burma, in the Philippines, Siberia, and among the Jumpers of North America. Fletcher has rightly drawn attention to the fact that, while the disease is very common in the Malay States it is, apparently, rare in the Malays who have emigrated. Thus, for example, it does not occur among the large colony of Malays in Ceylon, which may be due to the fact that they originally came from Batavia in Java, and not from Malaya, but it is said by Fletcher to occur in Chinese, Tamils, and in Europeans living in Malaya. The Ikota or Samoyeds, and the Tigretier of Abyssinia, are said to suffer from similar symptoms. In children the disease is milder than in adults.

Ætiology.—The exciting cause appears to be any sudden start, producing some peculiar movement, after which any unlooked-for action may be imitated, and is generally accompanied by bad language. The mildest form of the disease is merely an exclamation or a scream when startled, but in severe cases the patient will imitate any sudden motion or obey any suggestion made to him.

Fletcher relates that in some parts of the Malay States it is occasionally impossible for a judge to examine the witnesses, as they can do nothing but imitate and repeat the questions put to them.

According to Abraham, the exciting causes are: (1) Auditory—*e.g.*, an unexpected noise behind the person; (2) visual—some unlooked-for movement; (3) tactile, such as a sudden touch.

The predisposing cause would appear to be racial.

Symptomatology. On hearing an unexpected noise, seeing or performing a sudden movement, or being surprised by a touch, the patient repeats either the action seen or the words uttered, and at the same time may use foul language. The unfortunate victim is generally conscious of his words and actions, of which he may be ashamed, but he is quite unable to control them. The most graphic account of the symptomatology of the fully-developed complaint is that given by Sir Hugh Clifford in his 'Brown Humanity,' from which we are kindly permitted to give an extract. The disease is best seen in the Malays, and as no white man knows these people as Sir Hugh Clifford knows them, the following is of peculiar value:—

> 'The most typical case of lâtah within my experience was that of a Selangor Malay named Sat, who, in 1887 and 1888, cooked the rice for me and for ten, twenty, or thirty Malays who were then living in my house at Pekai. He was a great big, heavy-featured, large-boned, clumsily-built fellow, very solid, very stupid, very phlegmatic—the last person in the world one would have thought to be the victim of any nervous disorder. To the lay mind any abnormal degree of sensitiveness should be accompanied by a somewhat ethereal physique, a delicate skin, a blue-veined forehead, tiny hands and feet, and a highly-strung organization. To none of these things could poor Sat lay any sort of claim; and though, no doubt, doctors will say that these are by no means invariable accompaniments of a highly nervous temperament, I must own that Sat looked vastly improbable as the possessor of anything so rarefied. All the other Malays in my household were accustomed to put upon Sat most unmercifully, making him do almost the whole of the work that should rightly have been shared between them all. Sat never appeared to resent this arrangement, and he never made any complaint to me then, or at any later time, of the manner in which his fellows treated him.
>
> 'He spent almost the whole of his day in the great ramshackle room, built out over the river on supporting piles of nibong, in which the large wooden box, filled with baked clay, which served as our simple cooking-range, occupied the chief place in the centre of the tala floor.
>
> 'When the others were most noisy, Sat was still silent. When some of my men boasted of the great deeds they had performed in the old days in Selangor, Sat would listen obediently to the thrice-told tales, stolidly, but without excitement. Most of the other men had their own particular chums, but Sat was always solitary, and he never appeared to have any ideas in that great bullet-head of his which he desired to exchange with his neighbours.
>
> 'He had been an inmate of my hut for nearly a year before anyone discovered that he was lâtah. The fact came to light quite accidentally, Sat being startled out of his self-possession by the sudden capsizing of a cooking-

pot over which he was watching. A boy who chanced to be alone in the cook-room with Sat made an instantaneous grab at the fallen rice-pot, and in an instant Sat's hand was in the fire, grasping the burning hot metal. He withdrew his flayed fingers quickly, as the pain brought to him consciousness of what he had done, and he carried them at once to his head—that queer, groping, scratching motion which is an invariable accompaniment of lâtah—and the boy at his side needed no man to tell him that Sat was a victim to that extraordinary affliction.

'With the wanton cruelty and mischief of his age, the boy once more made a feint at the smoking rice-pot, and again Sat's fingers glued themselves for a moment to the scalding metal, and returned aimlessly to his head.

'I do not know how many times this was repeated, but Sat's fingers were in a terribly lacerated condition when at last someone chanced to enter the cook-room, and interfered to prevent the continuation of Sat's torture.

'After that, though I did all I could to protect him from molestation, Sat was never, I fancy, left in peace for long by the other men of my household. Gradually, in the course of a couple of months or so, this man, who for nearly a year had shown no signs of being the victim of any nervous disorder, was reduced to a really pitiable condition. The occasional lâtah seizures, which were at first induced by the persecutions of his fellows, ceased to be abnormal phases, and became the chronic condition of his mind. If one spoke to him, with no matter how much gentleness, he would repeat the words addressed to him over and over again, aimlessly, unintelligently, without, apparently, comprehending their meaning, and that wandering, groping hand of his would steal to his head, and scratch helplessly at his close-cropped hair.

'"Sat, listen, Sat!" I would say to him as quietly and as reassuringly as I knew how. "Listen! no man is worrying thee. Try to listen to what I say to thee." Sat would make answer, and then, very low, in a whisper under his breath: "Listen, listen, listen, listen, listen what I say to thee."

'I instituted a fine for anyone who was found annoying Sat, but it was impossible to get a conviction, for the unfortunate victim could never say who the man was who had teased him into a more than usually severe paroxysm of lâtah.

'It was about this time that a number of other people in my household began to develop signs of the affliction. I must not be understood as suggesting that they became infected with lâtah, for, on inquiring, I found that they had one and all been subject to occasional seizures when anything chanced to startle them badly long before they joined my people, but the presence of so complete a slave to the affliction as poor Sat seemed to cause them to lose the control which they had hitherto contrived to exercise over themselves. One of the older men among my people—Pa'Chim, we called him—a Malay by birth, and of some standing with his fellows, came to me and begged that I would see that no one did anything to give him a sudden start, since, he said, only a very little was needed to make him lâtah also. Yet this man, neither then nor later, showed any signs of the affliction. He probably exercised a considerable amount of self-control, but I always knew that in a moment I could have broken through his guard, and have startled him into as complete a seizure of lâtah as those of which Sat was the victim.

'One day a curious thing happened, which I will relate as it occurred, though I only witnessed the end of the incident.

'A Trĕnggânu Malay, who had a cousin among my people, came in to visit his relative, and chanced to find no one but Sat in the house. The latter invited the Trĕnggânu man to partake of sîrih, and they squatted down on the pĕntas, or raised eating-platform, in the centre of the house, with the sîrih-box between them. The villainous small boy, who had first discovered Sat's weakness was playing about in the room, and in some unholy way he had learned that the Trĕnggânu visitor was also a lâtah subject. He seized a long rattan, which, I think, was kept in the room by one of the older men for his occasional correction, and smote the sîrih-box as it lay between the two betel-chewers, making the wooden covering resound with the smart blow. The sudden and unexpected noise at once deprived both men of all power of

> self-restraint. Each gave a sharp cry and a " jump "—to use the colloquial expression—and, since there was nothing to distract their attention from one another, they fell to imitating each the other's gestures. For nearly half an hour, so far as I could judge from what I learned later, these two men sat opposite to one another, gesticulating wildly and aimlessly, using the most filthy language, and rocking their bodies to and fro. They never took their eyes off one another for sufficient time for the strange influence to be broken, and at length, utterly worn out and exhausted, first Sat and then the Trĕnggânu man fell over on the platform in fits, foaming horribly at the mouth with thin, white flakes of foam. Men came running to me for help, many having witnessed the end of this strange scene, and when I had doctored Sat and his companion back to consciousness, I tried to ascertain from them how they had come to fall victims to this seizure. They could tell me nothing, however, for they only remembered that before their trouble came upon them they had been chewing betel-nut. The matter was sifted out, none the less, and the small boy who had been the cause of the trouble again made the acquaintance of the piece of rattan, and, to judge by his cries, found the interview an unusually painful one.'

From the above account it will be seen that a sudden action will inhibit the higher centres and produce reflex movements in imitation of those performed by the exciting cause. The loss of memory of what has taken place and the peculiar movement of the hand to the head indicates the abrogation of the higher powers.

Varieties.—There are two varieties of the complaint—the impulsive and the mimetic. The former, produced by a sudden shock, results in violent action or bad language, of which the patient may be very ashamed. The mimetic is the form in which the sufferer, no matter how unwilling, is compelled to imitate.

Allied Complaints.—Lâtah must be closely related to those curious, psychical phenomena seen at times among different races, the afflicted people being variously known in Europe as ' the Jumpers,' ' the Barkers,' and ' the Jerks,' and must also be allied to those states of excitement into which people pass during times of religious revivals. In our experience it has also a certain resemblance to some cases of so-called ' Maladie de Gilles de la Tourette,' the main symptoms of which are echolalia and coprolalia.

A peculiar psychical outbreak took place in Madagascar in the years 1863-64 among the women of the lowest classes, consequent on the profound sensations caused by the violent death of King Ramada II., and the subsequent changes in the religion and laws. This outbreak is said to have been identical with the dancing mania of the Middle Ages. It is interesting to remember that there is a strong admixture of Malay blood in the natives of Madagascar, especially in the ruling classes.

It is thus seen that the condition, though at present most marked among the Malays, is, and has been, world-wide in its spread, and is really due to the possession of feeble higher centres which are easily upset, and then are unable to control the lower centres in the accustomed manner.

Diagnosis.—The diagnosis of lâtah is based upon the individual uncontrollably performing or imitating actions, often with echolalia or coprolalia.

Prognosis.—Lâtah is said never to end in insanity.

Medico-Legal.—With regard to the medico-legal aspect of lâtah, Fletcher has performed an experiment with a severely affected subject, proving that suggestion can compel a lâtah subject to commit a crime even against his will. He concludes that in lâtah crime is a possibility either as—

1. An act resulting from an imperfectly controlled inco-ordinate reaction to a sudden impulse; or as—

2. An act resulting from the suppression of volition in the severe forms, the determining cause of which is a criminal suggestion by a second person.

In evidence of the first, he cites two Malays going through a forest carrying their knives for cutting wood. A twig suddenly snaps, and the first man falls to the ground, which so upsets the second one that he also falls to the ground, and in so doing accidentally wounds the first man with the knife he is carrying. In evidence of the second, he places a dummy in a bed previously occupied by a friend of a lâtah person who had been removed without the latter's knowledge. Suddenly the lâtah person was ordered to take a knife which was placed in a handy position, and stab the dummy in the bed. The lâtah person tried not to do this, but was compelled to obey the suggestion. Thus, it would appear that there may be a near connection between lâtah and crime.

Treatment.—The treatment is most unsatisfactory, but auto-suggestion might be tried. Abraham states that some patients have cured themselves by determination not to succumb.

BANGA.

Definition.—A hysterical condition, chiefly influencing women above the age of puberty, but also occurring in men in the Welle District of the Belgian Congo.

Symptomatology.—Fright or anger may induce an attack, in which the body is shaken by convulsions, followed by wild cries and rushes out into the open country or forest away from frequented paths. Sometimes it is accompanied by aphasia.

Diagnosis.—It is said to be separable from hysteria by the absence of the stigmata of that disease.

Treatment.—Suggestion appears to cure these cases.

SCHAMANISMUS.

Schamanismus is the condition of excitement into which certain of the Dayaks and other peoples are able to throw themselves for religious purposes. This state of excitement seems to be attained by leading an extremely erotic life, and appears, by its singing, shrieking, and dancing to utter weariness, to resemble the dancing mania of the Middle Ages, and, therefore, to be related to lâtah.

ÂMOK.

Definition.—Âmok is a psychical disturbance, which, after a period of depression, suddenly develops into a violent attempt to kill people, of which no memory may be left, and after which a stuporous condition supervenes.

Remarks.—Âmok, which means 'an impulse to murder,' is a disease frequently found among the Malays, but also occasionally in other Oriental races. Abraham thinks that there may be some relationship between âmok and lâtah.

Climatology.—Âmok is found in Malaysia among the Bugis of Celebes, the Malays of Indo-China, Malacca, and the Malay States. It is also said to occur at times in Trinidad and among the inhabitants of India and Siberia.

Ætiology.—The exciting cause appears to be a strong emotion of anger, sorrow, or fear, after which a pause or incubation period of depression follows, which may last for days or weeks, during which the patient broods over his wrongs. The Dutch believe that it is induced by opium smoking, and Miall that it is due to smoking haschisch (*Cannabis indica*); but these causes are insufficient.

Symptomatology.—The attack is ushered in by colour sensations of red or black, with or without vertigo, and the patient complains of the appearance of devils, which he attempts to kill. The âmoker usually rushes out of his abode and attacks friends or foes, young or old, males or females, with his kris, or flame-shaped knife, or by firing on them with a gun. The attack usually lasts but a short time, and the deeds performed during that period are not remembered. After the attack the patient passes into a stuporous condition or deep sleep, which may last for a long time, after which he remains in a peculiar excitable condition for some months.

Allied Complaints.—This is a curious pathological entity, and may be a genuine psychical obliquity closely related to those epileptoid seizures investigated in Europe by Lombroso.

Medico-Legal.—If a case is considered genuine, the patient must not be regarded as responsible for his actions, but each case should be judged on its own merits.

Treatment.—No treatment has so far been tried in the prodromal stage, as far as we know.

TROPICAL NEURASTHENIA.

No disease among Europeans in the tropics deserves more careful study by the practitioner than neurasthenia, because, though not in itself fatal, still it leads to many of the petty worries felt and bad tempers exhibited, and, in worse cases, may seriously hamper good work being performed. The subject has been ably studied by Fales in Americans returning from the Philippine Islands.

Ætiology.—Tropical neurasthenia is apt to develop in white people in any part of the tropics, but especially in those which are subject to moist heat, and in some cases an important predisposing cause is the sun's rays, the effects of which are often disregarded. Moreover, the white man is generally compelled to work hard throughout the heat of the day, and is often exposed to the midday sun. The liability to the disease increases with the length of residence in the tropics. Predisposing causes are any previous illness, alcoholism, and overwork. Fales states that he found 30 per cent. of the men and 50 per cent. of the women who had resided for a year or longer in the Philippine Islands the subjects of such severe neurasthenia as to be semi-invalids. In our experience the disease is extremely common all over the tropics in Europeans as well as in the natives of the educated class.

Symptomatology.—In addition to the ordinary signs of neurasthenia, the tropical form seems to markedly affect the vascular system; palpitation is very common, and the patients suffer from various kinds of phobia, especially relating to diseases of the tropics.

Treatment.—The best treatment is rest and change of climate and mild hydropathic treatment. If this is not possible, hypodermic injections of sodium glycero-phosphate—0·1 gramme daily in bad cases—or some form of glycero-phosphate, with or without polyformates, by the mouth in mild cases, may be tried. The patient should discontinue cold baths, and should use warm baths, which should be taken at night if there is sleeplessness. Bromides are occasionally useful.

Prophylaxis.—As in some cases the disease is predisposed by exposure to the sun, protection is required against the sun's rays by topees lined with red, and, if necessary, by red underclothing or clothes made from the 'solaro' fabric already mentioned, and by avoidance of the midday sun as much as possible, and the total abstinence from alcohol.

Persons who are compelled to work hard under unfavourable conditions require change to the Temperate Zone at relatively short intervals—*i.e.*, about once in two or three years.

ENDEMIC PERIPHERAL NEURITIS.

Synonym.—Akatama.

Definition.—Endemic peripheral neuritis is a disease of unknown origin, characterized by numbness and intense prickling and burning sensations in the presence of cold or damp, which are temporarily relieved by the application of dry heat.

History.—The disease was first noticed by Wellman in Central Africa in 1896, and described by him in 1903. It affects 3 to 5 per cent. of the Bantu people, who are by profession porters, and are much impeded in their work by this complaint, which affects young and old, male and female alike. Their staple food is maize, which is eaten partially cooked.

Climatology.—The disease is found in that plateau of Africa which is 5,000 to 6,000 feet high, and is situated between 13° to 14° south latitude, and is inhabited by the Bihé, Bailundo, and Andulu peoples, all of whom are Bantus.

Ætiology.—Wellman was unable to find any causative organism in the blood or fæces. Some of the natives also suffered from filariasis, ankylostomiasis, and bilharziosis, but these were adventitious. His theories are that it may be caused by cold, fermented maize, or nerve-starvation; but he is not satisfied with any of these hypotheses.

Morbid Anatomy.—In bad cases there is some swelling, erythema, and slight œdema of the affected part; still, biopsies of the skin revealed nothing, and post mortem the nerves were found normal.

Symptomatology.—The disease usually begins with shooting, pricking, or crawling pains in the legs and forearms, accompanied by numbness, together with an erythematous rash and swelling of the affected area. All these symptoms are increased by cold and damp, and diminished by heat and dryness. They may also appear on the thighs and arms, and occasionally on any part of, or all over, the body. The gait is peculiar, the patient appearing to walk on the toes and heels. The disease may last for years, but spontaneous recovery is known.

Diagnosis.—The diagnosis is easy, for it is distinguished from beri-beri by the absence of pain in the calves, by the absence of the heart symptoms, and of the paralysis; from elephantiasis by the swelling being transitory; from malaria by an examination of the blood; and from pellagra by the symptoms improving during the warm season.

Prognosis.—This is good as to life and general health, though the course of the malady may be very protracted.

Treatment.—No method of treatment is known to do any good.

ERYTHROMELALGIA TROPICA.

Under this term Gerrard describes a nerve condition in which natives who work barefoot on roads and plantations in Malaya complain of a feeling of pins and needles in the soles of the feet, followed by an acute burning sensation, which prevents walking and sleeping. Malaria is assigned to be the cause. The treatment recommended is to place the feet in hot salt-water, which is said to give great relief.

DESERT HALLUCINATIONS.

Synonym.—Le Ragle.

D'Escayrac de Lauture describes hallucinations of the senses of sight, hearing, smell, or taste, or even of common sensations, which attack persons suffering from exhaustion in deserts. The causation is probably inanition. Generally the attack comes on at night, but it may occur in the day-time, when it is considered to be more serious. Usually hallucinations are visual, and thus stones look like buildings or large rocks, while caravans or files of soldiers may be seen which do not exist. It has nothing to do with true mirage.

Chalmers has met with a case which occurred in the Egyptian deserts, in which the attack at first only came on during the night, but once occurred in the day. Its causation appeared to be due to very hard work and mental worry. The symptoms quickly disappear under the influence of rest, better food, and cessation of worry.

EMOTIONAL EXCITEMENT.

Synonym. Misala.

Howard, in a very interesting paper, has recorded cases of emotional excitement called 'misala,' which vary from an attack of tropical anger to a condition almost bordering on mania, which can be controlled by authoritative commands, or which, left to themselves, pass off in a few hours or days. It occurs among the young adult males of Nyassaland.

DELUSIONS.

Delusions of poisoning and of bewitchment are common in Africa and Asia, and probably elsewhere, and are common explanations of various forms of disease or of hysteria.

AUTO-SUGGESTION.

Every practitioner in Africa and Asia is acquainted with the extraordinary ease with which a native can die if he makes up his mind to do so. The actual cause of death is often exhaustion due to starvation. It should be treated by suggestion.

CHAPTER XC

DISEASES OF THE ORGANS OF SPECIAL SENSE

General remarks—Diseases of the eye—Diseases of the ear—Diseases of the nose—References.

GENERAL REMARKS.

It is not usual to consider the diseases of the organs of special sense in a work on tropical medicine, but all the diseases of the tropics are being carefully studied at the present time, and therefore we are of the opinion that a few cursory remarks on the above subjects, from the point of view of the general practitioner, may be of some interest.

DISEASES OF THE EYE.

The history of the study of eye disease in the tropics has still to be written, but anyone interested in the general history of this branch of medical science is referred to Hirsch, 'Geschichte der Augenheilkunde' (Leipzig, 1877), which, though issued as a separate little volume, was originally part of Graefe's and Saemich's 'Handbuch der Augenheilkunde,' vol. vii. In this book there is an account of the ophthalmology known in ancient Egypt and India, as well as the history before and during the Alexandrine period of medical development. It will suffice to say that eye disease is described and treated in the Ebers papyrus, and that Suśruta mentioned 76 diseases of the eye, of which 9 were of the joinings of the eye, 21 of the eyelids, 11 of the sclerotic, 4 of the black part of the eye, 17 of the eye in general, 12 of the true organ of vision, and 2 were injuries. In recent years the work of the ophthalmic surgeons of India and Egypt and elsewhere has been beneficial, not merely in an extension of knowledge, but more importantly in benefit to the communities of the lands in which they live. Excellent work has been done by the travelling ophthalmic hospitals, such as those provided by private generosity in Egypt, which go from district to district. By this means, natives at a distance from main hospitals are enabled to obtain expert advice and treatment, which can be carried on in the interval between a visit by the local hospital and dispensary.

Another excellent institution of more or less recent origin is the Central Ophthalmic Hospital, to which the patient can be sent or more prolonged expert treatment. A model hospital of this nature can be found in the Victoria Eye Memorial in Colombo, Ceylon. The prevalence and importance of eye disease in the tropics cannot be too strongly insisted upon. The cases of ophthalmia are so frequent that it has been stated that in no region of the world is conjunctivitis so common, which may be due to the high temperature which favours the growth of micro-organisms; to the overcrowded and filthy native dwellings, which favour their dissemination; to the dirty habits of the lower-class natives; and to the presence of large numbers of flies at certain seasons, which also materially assist in the spread of infection from the diseased to the healthy. Moreover, these factors are reinforced by the irritation caused by the glare of the sun, and by the dust. Blindness is also very prevalent in the tropics. Denham, in his report on the census in Ceylon in 1911, states that, in a population of 4,106,350 persons, there were 3,957 blind persons, which figures, when analyzed, showed that there were 11 blind men and 8 blind women in every 10,000 men and women in Ceylon. In India, in 1901, there were 12 blind men and 12 blind women per 10,000 of each sex; while in England, in 1901, there were 8 blind men and 7 blind women per 10,000 of each sex.

Dr. Andreas Nell, in his statistics of the Victoria Eye Memorial Hospital in Colombo, Ceylon, for the years 1906-1918, shows that the causes of blindness in Ceylon may be classified as follows:—

Congenital Causes.—These included malformations of the eyeball, and syphilis acting upon the optic nerve, retina, and choroid.

Local Eye Diseases.—Ophthalmia neonatorum, Purulent ophthalmia in adults, Catarrhal ophthalmia, Granular ophthalmia, Ulceration of the cornea, Severe paralysis of the ocular muscles, and Glaucoma.

Traumatisms.—Injuries from sticks, thorns, and edges of leaves in the jungle, from spikes in the paddy ear, from the tips of the blades of water-grasses. Some of these injuries are at first trifling, but may become septic, and so cause blindness.

Constitutional Diseases.—These include syphilis, malignant tumours, leprosy, tuberculosis, and enteric fever, but malarial cachexia was not met with as a cause of blindness, nor was ankylostomiasis.

Drugs.—Alcohol (most common); tobacco (rare); quinine and opium (very rare).

There can be no doubt that blindness arises from neglect of the trivial cases of eye disease, and from septic infection, and that, as medical aid becomes more readily available and hygiene is improved, this serious affliction will diminish in the tropics.

For the purposes of the few remarks which we propose to make it will be convenient to divide the subject into: A. Eye Diseases Proper; and B. Eye Complications of Tropical Diseases.

A. EYE DISEASES PROPER.

Œdema of the Eyelids.

Under this term Chalmers and Marshall mention the acute swelling of the eyelids in Europeans and natives in Khartoum. The affected area shows the mark of a bite, and may perhaps be due to an ant, perhaps of the genus *Monomorium* Mayr, 1855.

Congenital Defects.

These are by no means uncommon in the tropics, and our experience includes cases of apparent anophthalmus or microphthalmus, coloboma, and albinism.

Colour Blindness.

This is of importance, and natives who are to be employed as pilots or on railways should be examined as to their power of distinguishing colours; and, indeed, if this has been neglected, it is advisable to examine the existing employés, as the results of such examinations are sometimes surprising. In testing, only the Eldridge-Green lamp and method should be used.

Errors of Refraction.

A subject which has begun to attract a considerable amount of attention is the condition of the eyes of native children in the more modern and higher class native schools, as regards errors of refraction; but the medical inspection of native schools in the tropics is at present neglected, though the children suffer from what may be termed book hunger, and so strain their eyes excessively.

Foreign Bodies.

In addition to the usual foreign bodies met with in the Temperate Zone, small flies are apt to get into the eye in the early evening, and some of these are very irritating, and may cause congestion; or, by introducing micro-organisms, conjunctivitis. Chalmers and Marshall record the finding of a small ant, *Monomorium bicolor* var. *nitidiventre*, firmly fixed by its jaws on to the ocular conjunctiva in a person in Khartoum.

Pterygium.

In this disease the pinguecula, being irritated, spreads on to the cornea, and carries the conjunctiva with it, thus giving rise to triangular folds extending from the ocular conjunctiva to the cornea on the inner or outer aspects of the eye. It is very common in the tropics, especially among coolies in Indo-China.

The treatment is removal.

Hyperæmia of the Conjunctiva.

This is extremely common, being caused by the glare of the sun or by the dust, especially in sandy regions, and is especially apt to occur in persons who have some slight, and perhaps unnoticed, error of refraction. It is also more liable to occur in persons who have some congestion of the naso-pharynx, and is one of the symptoms of rhinitis spastica vasomotoria. Usually the symptoms are but slight, but the eyes are inclined to water; this is aggravated by exposure to light, while the patient may complain of a slight feeling of grit in the eye or of a burning sensation.

On examination, a portion of the palpebral and of the ocular conjunctiva is seen to be congested, while the secretion from the Meibomian glands is noticed to be increased in amount and the eyes to be watery. Treatment consists in bathing with warm 2 per cent. solution of boric acid, in giving the eye rest, and in wearing neutral-tinted or yellowish-tinted glasses (Xanthophylline), which can be obtained in three strengths—light, medium, or strong.

Conjunctivitis.

This is extremely common in the tropics among natives and Europeans, and may be clinically subdivided into—(1) Conjunctivitis catarrhalis; (2) Conjunctivitis gonorrhoica; (3) Ophthalmia neonatorum; (4) Conjunctivitis trachomatosa; (5) Epitheliosis desquamativa; (6) Conjunctivitis phlyctenulosa; (7) Conjunctivitis vernalis. Diphtheria is not common in the tropics, and diphtheritic conjunctivitis is rare, while conjunctivitis nodosa is extremely rare, but can be caused by caterpillar hairs, or plant hairs, becoming embedded in the conjunctiva.

Conjunctivitis Catarrhalis.

This may be subdivided into the acute, the ronic, and the follicular forms.

The Acute Variety.—This is very common in the tropics, where it may occur in epidemics. The most common cause is the Koch-Weeks bacillus, which may induce a very severe form of inflammation; while almost as frequently the Morax-Axenfeld bacillus causes a milder though more prolonged attack, often called angular conjunctivitis. Rarer causes are the pneumococcus and staphylococcus. The small eye fly of Ceylon is suspected by Castellani and Perry of being an agent in the spread of this disease in Colombo.

The disease begins with photophobia, burning and itching in the eyes, with a sensation of grit, all of which symptoms are more pronounced in the morning than in the evening, when the eyelids are often glued together by the dried conjunctival secretion.

On examination, the palpebral and ocular conjunctivæ are seen to be red and congested, and sometimes to be marked by red spots indicative of small hæmorrhages, while the conjunctival secretion is increased in amount and may have particles of mucus swimming in it, or it may be largely composed of mucus, or in severe cases it may be purulent. Usually both eyes are attacked. The disease may disappear in eight to fourteen days if untreated, but more usually it becomes chronic. The complications most commonly observed are corneal ulcer and iritis.

The best treatment in severe cases is to evert the eyelids, and to lightly mop the inflamed conjunctiva with 2 per cent. solution of silver nitrate, followed by a weak solution of salt, or by instilling a

10 per cent. solution of protargol, or 10 to 25 per cent. of argyrol. Ice compresses are very soothing. For the inflammation due to the diplobacillus of Morax and Axenfeld, the best treatment is to instil a 0·25 per cent. solution of zinc sulphate two or three times a day, or a 0·50 per cent. solution once a day. When the acute symptoms have subsided, a little adrenalin may be added to the zinc sulphate solution.

In order to prevent the sticking together of the eyelids, a 2 per cent. ointment of boric acid, or a ½ per cent. strength of white precipitate ointment, may be used.

It is almost unnecessary to state that no bandage should be applied to the eye, or that the disease is contagious, and that it is necessary to warn the patient's friends of the danger of the attack.

The Chronic Variety may be the sequela to an acute attack, or may be in the form of the angular conjunctivitis due to the Morax-Axenfeld bacillus, or due to eyestrain or local injury by wind, dust or foreign bodies, or the use of alcoholic liquors.

The symptoms are most marked at night, when the patient feels as though a foreign body was in the eye or has sensations of rainbow colours. The eyes are apt to burn and to be dazzled by light. In the morning the lids are stuck together. Sometimes there is excessive secretion, and sometimes there is lessened secretion. If neglected, this chronic variety may last for years, and may lead to epiphora, ectropion, or ulceration of the cornea.

The treatment is the same as for the acute stage, but the best therapy is the zinc sulphate drops in the form of a ½ per cent. solution applied night and morning.

The Follicular Variety may occur in epidemics, and may be acute, when it is usually of bacterial origin; or chronic, when it is usually non-bacterial. It is characterized by the formation of small, round, pale granules about the size of a pin's head, and is easily mistaken for conjunctivitis trachomatosa; but the granules are usually best marked in the inferior fornix, while those of trachoma are more marked in the superior fornix and tarsus, which must be most carefully examined by retroverting the lid and the retrotarsal fold in order to be certain that trachoma is absent. In the acute form the treatment is *the* same as for acute catarrhal conjunctivitis, but when chronic it is usual to apply copper sulphate treatment. An ointment of 1 in 1,000 copper sulphate or 1 in 100 copper citrate is recommended by some authorities.

Conjunctivitis Gonorrhoica.

This is so well known that no special reference need be made to it.

Conjunctivitis Neonatorum.

This is usually due to the gonococcus, but may be caused by a streptococcus or probably by a chlamydozoon.

Micrococci and Conjunctivitis.

The presence of Gram-negative micrococci may be due to infection from the generative organs by the gonococcus, but it may also be due to infection from the nasopharynx via the lachrymal ducts by the meningococcus and the *Micrococcus catarrhalis*, which is merely a term for a group of Gram-negative cocci. The Gram-negative cocci of the conjunctiva may be roughly separated from one another by cultivation in sugar media.

Organism.	*Glucose.*	*Maltose*
Gonococcus	+	–
Meningococcus	‡	‡
Micrococcus catarrhalis	–	–

Acid only, +; acid and gas, ‡; neither, –.

Conjunctivitis Trachomatosa.

Synonym.—Ophthalmia Ægyptiaca.

This is exceedingly common in China, where 70 per cent. of the children in Hong Kong are said to be infected. It is also common in many other parts of the tropics, especially in India, Japan, and South America; but it is also prevalent in North Africa, especially in Egypt, in South Africa, in Southern Europe, and in Porto Rico. It is an infectious disease, believed by many authorities to be due to a chlamydozoon described by Halberstaedter and Prowazek. A fungus—*e.g.*, the *Microsporon trachomatosum*—has been described by Noiszewski, which is only distinguishable from *Malassezia furfur* by the smallness of its conidia. With regard to the chlamydozoon, it occurs in the cytoplasm of epithelial cells as fine granules, which increase in size, and separate so as to enclose a cavity at first free from granules, in which subsequently very minute granules appear.

Probable Ætiology.—There is a growing suspicion that trachoma is essentially a disease arising from chronic urethritis in men and chronic vaginitis in women, because cell-inclusions of a chlamydozoan nature have been found by several observers in the discharge from the urethra of men suffering from gonorrhœa, while Castellani has found similar inclusions in a man in Colombo who is believed never to have had gonorrhœa. Further, similar bodies have been found in the vaginal discharge of women whose children have suffered from the form of ophthalmia neonatorum in which no gonococci or streptococci can be found. Further, Castellani has found similar bodies in a case which may have been one of the rare acute inflammations of a pure trachoma without granule formation, and which may have been induced in the acute form because the woman in question was run down owing to the acute attack of malaria from which she suffered. This case emphasizes the fact that these bodies should be looked for in those so-called attacks of malarial conjunctivitis which are found associated with attacks of malarial fever. Finally, Lander has produced a chronic conjunctivitis by transferring the secretion of vagina and urethra mentioned above to monkeys. This experimental conjunctivitis was associated with the formation of granules clinically and anatomically resembling the conjunctivitis trachomatosa of man.

Method of Infection.—The infection is carried by the hands, towels, handkerchiefs, etc., from the sick to the healthy. There is no evidence of aerial transmission. The agency of flies in the transmission of eye disease has long been known—for example, Budd, in 1862, considered it proven that they transmitted ophthal-

[illegible] trachoma [illegible]

[illegible] are supported by a [illegible] This is a layer of [illegible] and bloodvessels. [illegible]

[illegible] acute attack may begin [illegible] great swe[illegible] purulent [illegible] the typical no[illegible] at first be absent. [illegible] with [illegible] the [illegible] is dim[illegible] the disease [illegible] with photophobia, pain, and watering of the eye; the lids stick together in the morning, and there is diminution of visual acuity. The eye is not fully opened, partly because of the photophobia, and partly because the upper lid is swollen and heavy. On everting the lids, the tarsal and transitional conjunctivæ are found to be swollen and red, and either velvety in appearance, or with distinct nodules which are most marked on the upper lid. These nodules or granules are of considerable importance in the differentiation between trachoma and follicular conjunctivitis, and it is to be specially noted that those of trachoma are larger in the superior fornix than in the inferior fornix. It is therefore important to examine the superior retrotarsal fold very carefully. On the tarsal conjunctiva the granules are not so prominent, and are therefore less easily seen. A trachoma granule is typically a grey, roundish, translucent granule, comparable to a grain of boiled sago in appearance. Harston's sign is a linear groove running almost horizontally [illegible] external canthus. The hypertrophy of the co[illegible] increases until some indefinite [illegible] reached, when it ceases and [illegible]cicatrization [illegible]; but if the [illegible]trophy is excessive, it may last for [illegible] develop slowly but surely.

The cicatrization shows itself at [illegible] whitish striæ on [illegible] conjunctivæ, which, becoming more numerous, unite [illegible] network; the meshes of which are occupied by the [illegible] conjunctiva, which gradually diminish as cicatrization proceeds; until the conjunctiva becomes pale in colour. In some cases this cicatrization is very slight and hardly noticeable, while in others it may produce serious complications.

The loss of vision is due to pannus and ulceration of the cornea, the former being a deposit of vesicular gelatinous tissue on the cornea, which becomes uneven and raised in fine projections; while the latter may occur with the pannus or separately.

The sequelæ of trachoma may be classified into:—

(*a*) Corneal ulceration and pannus, leading to *opacities*.

(*b*) Cicatrization, leading to (1) *Trichiasis*, in which the cilia are turned backwards and may touch the cornea; (2) *Entropion*, in which the border of the lid is turned backward; (3) *Ectropion*, in which the lid is everted; (4) *Symblepharon posterius*, in which the fornix is diminished in depth, and the lid is tightly fastened to the eyeball.

[illegible] Conjunctival xerosis, in which the conjunctiva, owing to atrophy, loses its secreting powers, and becomes dry and shrunken.

Treatment.—The acute cases are to be treated with silver preparations, as described for conjunctivitis.

When the follicles are well developed it is usual to express them by means of a flat Grady's forceps or by the roller forceps of Knapp, but this must be performed under an anæsthetic. The ruptured surface is then painted with a solution of perchloride of mercury and after one or two days' interval the daily application of solid copper sulphate is commenced, which may be applied pure or as a Canestou's crayon, which consists of sulphate of copper, 1·0 gramme; orthoform, 0·5 gramme; holocain hydrochloride, 0·5 gramme; gum tragacanth, 0·1 gramme; and water as may be required. The above are the quantities required to make a pencil 5 centimetres in length.

Harston strongly recommends treatment by carbon dioxide snow, which has produced excellent results in many hands, and as it has only to be applied once a fortnight is useful for general out-patient work. It is, however, very painful, and this pain is not prevented by cocaine, which therefore need not be used.

Hegner and Baumm have advised treatment by quartz light, while other methods are Galezowski's excision of the retrotarsal folds, Kuhnt's removal of the tarsus, while treatment by Merk's extract of abrin, Mayon's X-ray method, and Treacher Collins's radium treatment may be mentioned.

Epitheliosis Desquamativa.

Synonym.—Samoan eye disease.

Under the name Leber and von Prowazek have described a form of conjunctivitis which they met with in Samoa, where they examined and treated seventy-nine fresh infections. They consider the causation to be a chlamydozoon—*Lyozoon atrophicans* Leber and von Prowazek, [illegible] which is found in the milky secretion in the form of trachoma-like bodies, which, when coloured by Giemsa, show blue poles and a central lacuna. These bodies are either intracellular or extracellular. The intracellular bodies form what is commonly called a 'cell inclusion of small granules,' which take on a violet-red colour when stained by Giemsa, and are called the 'elementary bodies' and lie in the centre, while the larger initial bodies lie at the periphery. These parasites cause a hypertrophy of the cell nucleus, which eventually leads to an atrophy of the cell. The disease was conveyed to guinea-pigs.

The symptoms begin with pain, photophobia, and livid coloration of the upper and lower lids, while a milky secretion is poured out, which is composed at first of epithelial cells only, but may become purulent. Granules similar to those of trachoma do not develop, but atrophy of the conjunctiva ensues. The treatment recommended is pyoktanin in the proportion of 1 in 1 000 to 1 in 10[illegible]

Conjunctivitis phlyctenulosa.

This is not very frequently met with in the tropics. It is usually found in scrofulous individuals, and is characterized by the presence of small vesicles, each surrounded by a reddened zone.

Conjunctivitis Vernalis.

Synonyms.—Conjunctivitis Æstivalis, Spring catarrh.

Definition.—A chronic form of conjunctivitis, resembling conjunctivitis trachomatosa, but occurring in the spring and summer, and disappearing in the autumn and winter.

Remarks.—Spring catarrh is apparently not so rare in the tropics as in the Temperate Zone, as Nell informs us that he has met with thirty-eight cases in Ceylon.

Ætiology.—The cause is unknown, but some authorities consider that it is due to sunlight, while others hold that it is an infection from the skin.

Symptomatology.—On the approach of the warm weather in spring the eyes begin to itch and water. The conjunctiva becomes red, and photophobia is experienced. On examination the conjunctiva is seen to be covered with broad, flattened papillæ, over which a bluish-white film is seen. The affection lasts during the summer, wanes in the autumn, and disappears in the winter, only to recur in the spring.

Diagnosis.—The diagnosis must be made by the history and by the bluish-white sheen over the papillæ. It resembles trachoma, but the granules are broader, harder, and paler, while the history is distinctive.

Treatment.—Protective glasses must be worn, and zinc sul[illegible] lotion (½ per cent.) dropped into the eyes. If the itching is [illegible] severe, it is recommended to apply a few drops of a very weak solution of acidium aceticum dilutum. Iron tonics are also advised.

Epithelial Xerosis of the Eye.

This condition has been recorded several times from the tropics. Archibald has recently described very carefully three cases in the Sudan. The xerotic patches were situated on the conjunctiva external and close to the corneal margin of both eyes (Fig. 793). The patches were greyish-white in colour and of a soft viscid consistency; the superficial layers were readily removed with a platinum loop; the deeper layers, however, were more adherent to the subjacent epithelium, which showed a brownish pigmentation. The bloodvessels in the vicinity of the patches were congested. There was no evidence of trachoma or inflammation of the eyelids. The whole bulbar conjunctiva was moist, and could be readily moved into folds by gentle pressure with a platinum loop. There was an absence of pain or discomfort associated with the lesions, which appear to have had a duration of several years. Vision was not impaired, and there was no evidence of night-blindness.

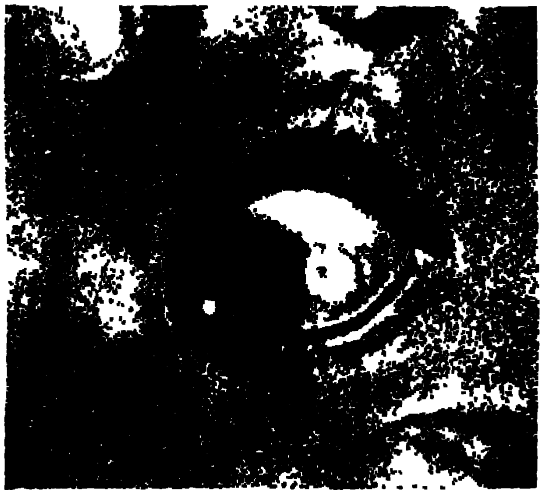

FIG. 793.—EPITHELIAL XEROSIS OF THE EYE.

(From a photograph by Archibald.)

Ætiology.—Scrapings from the xerotic patches showed the presence of a Gram-positive diphtheroid organism in large numbers which was obtained in pure culture from the cases. This organism (*B. xerosis* Neisser) differed from the true Klebs-Loeffler bacillus in its cultural reactions, and, moreover, was non-pathogenic to guinea-pigs.

Treatment.—Attention to general health and the administration of cod-liver oil internally is indicated. The affected eyes should be protected from light and daily douched with weak boric solution, followed by the application of a few drops of a 1 per cent. solution of protargol.

Lachrymal Sac.

The lachrymal sac, being in direct connection with the nose, is very liable to harbour micro-organisms and fungi, and is therefore a possible source of infection for the conjunctiva and cornea.

Cornea.

Phlyctenular keratitis is common as a sequela to conjunctivitis phlyctenulosa, both of which act as common predisposing causes to pterygium, which, according to Harston, is extremely common among the Chinese.

Ulcus Serpens Corneæ.

This appears as a greyish-white or yellowish slightly depressed disc near the centre of the cornea, the rest of which is clouded. It is associated with iritis and turbidity of the vitreous, hypopyon, and more or less œdema of the lids, with conjunctivitis, cyclitis, photophobia, and pain, except in the so-called 'torpid' cases. The ulcers increase in depth and extent; perforation occurs into the anterior chamber, which contains *sterile* pus, which now escapes, and at the same time prolapse of the iris may occur. The inflammation now comes to an end, but panophthalmia may occur. The most common cause in the tropics is the pneumococcus, which may often be found in the nose of the same patient. The prognosis is serious.

Treatment.—The cauterization of the ulcer and apparently clear border with the actual cautery is an imperative immediate treatment, followed by application of atropine, iodoform, or orthoform powder, or 1 per cent. xeroform ointment, or callaryol ointment 3 per cent., and moist and warm compresses. Harston recommends douching with hydrogen peroxide as an adjuvant to the usual treatment, while 1 in 40 formalin solution is also recommended, but must be preceded by cocaine, as it is very painful. Perforated ulcers are best treated by iridectomy on each side of the synechia. Harston operates on the worst eye of the two when both are involved, as operative interference is apt to set up a severe irido-cyclitis in the poorly-nourished Chinese coolie, with eventual loss of sight in the eye. The nasal infection must also be treated by antiseptic douches.

Iris.

Diseases of the iris are as common in the tropics as in the Temperate Zone. Those which are specially connected with tropical disease will be mentioned below, but it is well to remember that in native races the stroma of the iris is laden with pigment, which probably accounts for its slow reaction to mydriatics.

Cataract.

This disease is said to be on the wane in the Temperate Zone, but is very rife in the tropics. In fact, its home is said to be in India, the ophthalmic surgeons of which have a great reputation. Colonel Smith, of Jullundur, has perfected a complicated but most successful operation for intracapsular extraction.

Sometimes in the tropics it is impossible to wait until the cataract ripens, and operations may have to be performed on immature cataracts. To meet this difficulty, Nell has devised a modification of the usual procedure, which consists in performing a zonulotomy by means of a special hook introduced through the corneal wound made for a cataract extraction and under the iris. After this preliminary proceeding he completes the operation by intracapsular extraction of the lens.

Glaucoma.

Acute glaucoma is rare in the tropics, while chronic glaucoma is common; but the signs, symptoms, and treatment are the same as in the Temperate Zone. The Elliot operation of trephining, with or without subsequent iridectomy, is recommended.

Fundus Oculi.

The colour of the fundus oculi depends upon the amount of retinal pigment present and to a less degree upon the amount of the choroidal pigment visible. It therefore shows variations from the European standard in dark and yellow races. In these races the amount of retinal pigment is increased, and may completely conceal that of the choroid, and so produce a uniform yellowish colour, as seen in the Chinese; or a dark reddish, or even an almost greyish-red colour, as seen in the various negro races.

On the other hand, when the retinal and choroidal pigments are diminished, as in albinism, then the white sclerotic shows through, and the fundus becomes of a lighter red colour than normal.

Sunlight.

The effect of sunlight on the eyes has been studied by Sisson, who considers that there is ample proof that light injures the eye, and that it may possibly be the cause of some diseases of the eye, the ætiology of which is but little understood. Schmidt considers that nyctalopia and hemeralopia may be caused by excessive light. The use of protective xanthophylline glasses is recommended.

B. EYE COMPLICATIONS OF TROPICAL DISEASES

Malaria.

Malaria is held to be responsible for conjunctivitis, serpiginous corneal ulcers, malarial iritis, and retino-choroiditis, as well as amaurosis.

Until a few years ago, the majority of the fevers of the tropics, including enteric fever, were classified as malaria, and any local affection of an unknown nature was also classified in the same manner. The case of conjunctivitis in which one of us found cell inclusions would a few years ago have been named malarial. We are therefore of the opinion that the existence of malarial conjunctivitis has not been proved.

Keratitis Dendritica.—This keratitis is that variety of herpes corneæ febrilis (sometimes called 'herpes corneæ zoster') which gives rise to those ulcers (formed from the ruptured herpetic vesicles) which extend in certain directions only as grey forked striæ with lateral branches, which break down, thus forming a branched ulcer with grey margins. The ulcer then becomes clean, and heals after one to three months, leaving a branched opacity of the cornea. This is one form of corneal ulcer to which the name 'serpiginous' is given, but it equally applies to ulcus rodens and keratitis marginalis superficialis, which, as far as we know, have never been stated to be of malarial origin. Keratitis dendritica was first described by Kipp in America, who stated that nine out of every ten cases were malarial.

The treatment must be that described for malaria, as well as constitutional, and it is usual to recommend that the ulcers be treated by a piece of blue stone whittled to a fine point, and carried carefully along the furrow made by the ulcer, or by careful cauterization by the actual cautery.

Keratitis Profunda.—*Synonyms.*—Keratitis parenchymatosa circumscripta, or Central parenchymatous infiltration of the cornea.

This is said by Arlt, among other causes, to be brought about by chronic malarial cachexia. It begins with a grey opacity, situate in the middle and deep layers of the centre of the cornea, and over which the corneal surface is grey and punctate. Seen with a magnifying-glass, the opacity resolves into dots and maculæ, or grey interlacing striæ. After remaining four to eight weeks, it slowly abates without ulceration. The iris may be hyperæmic, and there may or may not be symptoms of inflammation of the cornea, which may recover completely, or with some opacity. The treatment would be the same as for malaria, but it must be definitely stated that the cause is unknown.

Iritis.—Secondary iritis is said to be very rarely caused by malaria, but even this is open to doubt.

Vitreous Opacities. Hæmorrhage and serous effusion have been described.

Amaurosis.—Malarial amaurosis is described in Chapter XI., p. 1181, under the term 'Amaurotic Pernicious Fever,' but may occur, not merely during an attack of malaria, but as a sequel, and as such was described by Jacobi in 1868, and later by Chiarini. It is due to atrophy of the optic nerve.

Retino-choroiditis.—This was first described by Poncet as occurring in chronic malaria, but it is also found in the acute and in the chronic forms. In the acute affection the vessels of the retina are filled with corpuscles, many of which contain malarial parasites. In the choroid the larger vessels contain pigmented leucocytes, many of which contain red corpuscles with malarial parasites. The retina is hazy, the papilla is obscured, and there are retinal hæmorrhages.

The amblyopia may be temporary or permanent. In the chronic condition there is atrophy of the capillaries of the choroid. The macular region shows small whitish dots, in the centre of which retinal pigment can be seen. These changes extend to the periphery. Pathologically, they are colloid masses in Bruch's membrane.

Suppurative Uveitis.—Suppurative choroiditis, leading to destruction of the eye, has only been described by Pennoff.

Accommodation Paralysis.—Accommodation paralysis and spasm of the muscles of accommodation have been described by Bull and Slitting.

Trypanosomiasis.

Choroiditis, cyclitis, iritis, and optic neuritis of a temporary nature are reported as occurring in sleeping sickness, as well as engorgement of the iris and loss of the light reflex, with wide dilatation of the pupil.

Relapsing Fevers.

Irido-cyclitis, or iritis, is a frequent complication of the relapsing fevers, and though it ultimately ends in a cure, it is usually protracted.

Plague.

Conjunctivitis is common in plague as an initial symptom; later a plastic uveitis with hypopyon and keratitis may occur, and call for special treatment by administration of mercury, local installation of atropine, and blood extraction by leeches.

Leprosy.

In tubercular leprosy yellowish translucent nodules of a nonvascular nature may develop in the conjunctiva near the cornea. Iritis and cyclitis, with or without the formation of nodules, may occur. According to Wood, more than half the anæsthetic lepers of South Africa suffer from eye complications—*e.g.*, paralysis of the orbicularis palpebrarum, ectropion of the lower lids, epiphora, corneal opacity, and ulcerations. Of the tubercular lepers he says 90 per cent. are affected in the first ten years of the disease, and if they survive they become blind. They suffer from invasion of the lids, conjunctivæ, sclerotic, cornea, and iris by the disease, and in addition may suffer from paralysis of the ciliary muscle and irido-cyclitis. Heymans finds lagophthalmos to be common. In 1915 Stanziale published experiments on the eye of rabbits, injecting leprotic material into the cornea.

Cholera.

Focal necrosis in the cornea and conjunctiva has been reported in convalescence from cholera, while a form of cataract depending upon the abstraction of water takes place at times in the last stage of the disease.

Dysentery.

Conjunctivitis, keratitis, iritis, and irido-cyclitis are reported in dysentery, both amœbic and bacterial.

Hikan.

Under this term a curious disease is described by various observers, among whom Jeanselme and Risb. The main symptoms appear to be hemeralopia, xerophthalmia, dryness of the skin, and diarrhœa occurring in young children in Russia, Brazil, and Japan. The causation is unknown, but treatment by cod-liver oil is said to be very efficacious.

Quinine.

Amaurosis associated with complete deafness may set in after doses of less than 1 gramme of quinine, though more usually after a dose of 3 grammes and upwards. The amaurosis gradually disappears, leaving an amblyopia with a much contracted field of vision. This result is due to a destruction of the ganglion cells of the retina by the quinine, after which a degeneration of the optic nerve sets in.

The symptoms are a blanching of the retina and disc, due to spasm of the vessels, and loss of the pupillary light reflex, the pupils being widely dilated. It should be differentiated from the malarial amaurosis. In the former the pupils are usually widely dilated, and do not react to light, while in the latter they do react to light.

The deleterious effect of therapeutic doses of quinine has often been exaggerated. Doses of 10 to 15 grains may usually be given three times daily for long periods of time without any damage to the eyes. Jamieson and Lindsay have noted that even when the visual field is found to be contracted, the prognosis is good and ultimate expansion of the field may be expected.

Atoxyl.

Sudden amaurosis may be caused by atoxyl.

Animal Parasites.

Ocular Paragonimiasis. Cysts containing *Paragonimus westermanni* have been reported as occurring on the eyelids and orbit, and so hindering the movements of the eyeball and obstructing the vision.

Ocular Filariasis. –*Loa loa* has been noticed in the ocular and palpebral conjunctiva (*vide* pp. 645 and 1972).

In addition to paragonimiasis and filariasis, the following parasites occur in the eye or its adnexa: *Agamodistomum ophthalmobium* Diesing, 1850; *Monostomum lentis* von Nordmann, 1832 (both of which may be stages of *Dicrocœlium lanceatum* Stiles and Hassell, 1896); *Sparganum mansoni* Cobbold, 1883: *Agamofilaria oculi humani* von Nordmann, 1832; *Agamofilaria palpebralis* Pace, 1867, *nec* Wilson, 1844; *Dermanyssus gallinæ* De Geer, 1778 (which may be seen as a dark spot embedded in the cornea): *Demodex folliculorum* Simon, 1842, which is found in the Meibomian glands, and may cause a blepharitis. The larvæ of *Dermatobia cyaniventris* Macquart, 1843, has been found by Malgahães under the palpebral conjunctiva and in the lachrymal sacs in Brazil. A larva of *Sarcophaga magnifica* Schiner, 1862, has been found in the anterior chamber of the eye, and a larva of a species of *Necrobia* in a sclerotic tumour; but for a fuller account of ocular myiasis see Chapter LXVII.

Cysticercus cellulosæ has been found in the choroid, which it may leave, and, passing under the retina, may cause detachment; later it may perforate the retina and enter the vitreous, or it may enter the retina or the ciliary region, and so pass directly into the vitreous, where it appears as a bluish-white bladder, with or without a protruded head. The eye may be destroyed by irido-cyclitis. Echinococcal invasion is very rare.

Ophthalmomycoses.

Definition.—Diseases of the eye and its adnexa caused by various fungi.

History.—The word mycosis was introduced by Virchow to signify a disease caused by fungi, being first used for aspergillosis of the lungs. The interest in fungi as causes of disease was first aroused by Gruby, who in 1847 appears to have noticed fungal structures in lachrymal concretions, although he did not publish his observations. Helmbrecht and Robin were the first to actually assign a disease of the eyes to the action of fungi. They observed a fungus, which they called *Leptomitus*, in a case of conjunctival inflammation associated with epiphora. In 1854 Graefe described the fungal nature of lachrymal concretions, and in 1874 Cohn showed that these fungi belonged to the genus *Streptothrix* (*Nocardia*). In 1879 Leber discovered the first case of keratomycosis caused by *Aspergillus fumigatus*. From this date until comparatively recently fungi went out of fashion, being replaced by interest in bacteria, but with the revival of interest created largely by Sabouraud eye diseases were again investigated, and in 1906 De Beurmann and Gougerot gave an account of ocular sporotrichosis, and in 1907 Danlos and Blanc of palpebral sporotrichosis, and Morax described a form of keratomycosis caused by *Glenospora graphii*, and Lagrange and Landrieu a form of conjunctivitis due to *Nocardia dassonvillei*, while in 1912 Landrieu reviewed the whole subject of ocular mycoses in a singularly able manner.

Fungi.—The following fungi have been recognized in various diseases of the eye:—

A. Order Ascomycetes.

- I. Suborder Gymnoasceæ.
  - (a) Family Saccharomycetes.
    - (1) Genus Cryptococcus.
      - *C. dermatitidis* Gilchrist and Stokes, 1898.
    - (2) Genus Saccharomyces several species.
  - (b) Family Gymnoasceæ.
    - (1) Genus Microsporon
      - *M. lanosum* Sabouraud, 1907
    - (2) Genus Trichophyton
      - *T. tonsurans* Malmsten, 1845, and other species of the same genus.
    - (3) Genus Achorion
      - *A. schoenleinii* Lebert, 1845
- II. Suborder Carpoasceæ.
  - Family Perisporiaceæ.
    - Genus Aspergillus.
      - *A. fumigatus* Fresenius, 1863

B. Order Hyphomycetes.

- (1) Genus Nocardia.
  - *N. bovis* Harz, 1877.
  - *N. israeli* Kruse, 1896.
  - *N. foersteri* Cohn, 1874.
  - *N. dassonvillei* Brocq Rousseau, 1907.
- (2) Genus Monilia.
  - *M. albicans* Robin, 1853, and other species of the same genus.
- (3) Genus Glenospora.
  - *G. graphii* Siebenmann, 1889.
- (4) Genus Sporotrichum.
  - *S. beurmanni* Matruchot and Ramond, 1905.

Pathogenicity.—The ocular diseases caused by the above fungi may be grouped as follows:—

Fungus.	*Disease.*
Cryptococcus dermatitis and various species of the genus Saccharomyces	Ocular Blastomycosis.
Microsporon lanosum Trichophyton tonsurans Achorion schoenleini	Ocular Tineæ.
Aspergillus fumigatus	Ocular Aspergillosis.
Nocardia bovis Nocardia israeli Cohnistreptothrix foersteri Nocardia dassonvillei	Ocular Nocardiases.
Monilia albicans and other species of the same genus	Ocular Moniliasis.
Glenospora graphii	Ocular Glenosporosis.
Sporotrichum beurmanni	Ocular Sporotrichosis.

Ocular Blastomycosis.

Ocular blastomycosis is seen in the form of **Palpebral Blastomycosis,** which begins as papules which increase in size and give rise to pustules covered with crusts, and, later, to a warty condition, which may become red, moist, and granular. In other cases a subdermal nodule is formed, which may ulcerate. The causal agent is *Cryptococcus dermatitidis* Gilchrist and Stokes, 1898. The diagnosis is made by culture of the fungus.

Ocular Tineæ.

Tinea palpebrarum may be caused by *Microsporon lanosum* Sabouraud, 1907, by various species of *Trichophyton*, of which that most commonly found is *T. tonsurans* Malmsten, 1845. These fungi may or may not attack the cilia. If they do so, then small yellow crusts will be seen surrounding a cilium. On the removal of these crusts, small pustules will be seen. When they do not attack the cilia, they give rise to herpetiform lesions on the eyelids proper. The diagnosis is made by culture of the fungus. The treatment consists in epilation, warm compresses, and tincture of iodine.

Achorion schoenleini Lebert, 1845, the fungus of favus, may also attack the eyelids.

Ocular Aspergillosis.

About two days after a slight traumatism to the eye, irritation is felt, followed by pains, and the formation of an abscess, and later an ulcer. The diagnosis can only be made by the microscopical or cultural examination of scrapings from the ulcer or of the pus from the abscess. The treatment consists in curetting and applying a lotion of silver nitrate and atropine drops.

Ocular Nocardiases.

Actinomycotic conjunctivitis was first described by Demichéri in 1899, actinomycotic corneal ulcers by de Bernardinis and de Donna in 1905, and miliary actinomycotic metastases in the choroid by Müller in 1903. Conjunctivitis due to *N. dassonvillei* has been recorded by Liégard and Landrieu in 1911.

Ever since the days of Céson in 1670 lachrymal concretions have from time to time been recorded, but their parasitic nature was not recognized until Gruby in 1848 found that they were really fungal in origin. This fungus is known to be *Cohnistreptothrix foersteri*. The concretions occur in the form of minute grains in the lachrymal sac, from which they can easily be removed.

Ocular Moniliasis.

Monilia albicans Robin, 1853, one of the organisms of 'thrush,' may very rarely attack the conjunctiva, as first described by Pichler in 1895. Cases due to *Monilia tropicalis* Castellani and other species have been seen by us in Ceylon.

Ocular Glenosporosis.

So far, only one case in the cornea is recorded. It was found in 1910 by Morax.

Ocular Sporotrichosis.

Sporotrichal infection of the eyelids, conjunctiva, lachrymal sac, and iris have been recorded, but are as yet rare. The first case was found in 1905 by Danlos and Blanc, the second case in 1908, the third in 1909. Four cases were recorded in 1910, and three in 1911, and several in 1912.

DISEASES OF THE EAR.

The diseases of the ear in the tropics require more attention than has hitherto been bestowed upon them. The majority are believed to resemble those found in the Temperate Zone. A few remarks will be offered with regard to the diseases of the auricle, of the external auditory meatus, and with regard to ear complications in tropical diseases.

The Auricle.

Deformities of the lobule are common among Indian girls and women, who drag the lobule into a long, pendulous loop by means of heavy golden ornaments, or, failing these, by pieces of other metals or even wood. A similar condition is reported by Castellani, Bland-Sutton, and others, as occurring among the Masai and the Kikuyu people of East Africa.

Nepaul Tumour.--In 1833, Campbell, and in 1835, Bramley, drew attention to a peculiar disease of the skin of the auricle which was endemic in the village of Nilkantha, situate in one of the Nepaul valleys, at the foot of the Sheopuri Hills. The disease begins as a small firm swelling of the skin on the external aspect of the auricle, which is elastic to the touch, and which increases until it reaches the size of a pigeon's egg in four to eight weeks. It is adherent to the subcutaneous tissues, but is slightly movable. If it grows rapidly, the superjacent skin becomes bluish, and a painful feeling of tension is produced. If the swelling is punctured, a thick whitish fluid exudes. It grows until it reaches the size of an orange or of a child's head, and it may attain such a size that it reaches to the patient's shoulder. After a time its contents soften and become absorbed, while the sac of the tumour shrinks, leaving the ear much thickened and shapeless. Usually both ears are affected, and sometimes a succession of tumours, one after the other, may take place. The causation is unknown. It is more common in women than in men. Campbell thinks that it occurs associated with goitre, which would suggest a parasitic causation, but Bramley is opposed to this view.

It is curious that there is so little literature on this subject, and that neither Scheube nor ourselves are acquainted with any further papers describing this disease.

Lipoma.—Lipoma of the lobule of the ear, often on both ears, is reported in Loango. This tumour may reach the size of a walnut or a child's head, and is thought to be due to the fact that the negroes bore their ears with thorns or with pointed strips of palm-leaves, which are retained in the lobe of the ear for some time.

Fibromata.—We have often met with soft small fibromata attached to the lobules of the ears of the negroes on the Gold Coast, which can readily be removed. Perhaps the lipomata of Loango are really soft fibromata.

Keloid.—Keloid is met with on the auricle in West African natives, arising after insignificant wounds, such as ear-piercing, etc., and may form large tumours.

External Auditory Meatus.

Foreign Bodies are commonly met with in the tropics, and may consist of animate objects, such as beetles, flies, etc.; or inanimate objects, such as pieces of wood, etc. Usually their presence can easily be determined by inspection, which should always be carried out before any treatment is resorted to. The first treatment should be to attempt to wash the body out of the meatus by means of hot boracic lotion and an ear syringe, unless the body be a pea, bean, or grain of maize, because these would become swollen with the water. Under these circumstances, it is better to instil some glycerine mixed with a little rectified spirit and solution of cocaine, which causes them to contract, when a camel's-hair brush dipped in thick collodion may be carefully applied to the object. After waiting a little time for the collodion to set, traction can be made and the object removed. Failing these, attempts must be made to remove the body by Guye's fenestrated forceps, Politzer's gouge forceps, Tröltsch's aural hook, an aural curette, or, in the case of impacted steel bodies, the electro-magnet. If there is much swelling of the mucous membrane of the passage, it may be necessary to apply a solution of cocaine and adrenaline, after which extraction may be attempted. It is often advisable to administer an anæsthetic if a body is impacted in a child's ear. If all attempts fail, an operation is necessary, which is generally performed by detaching the auricle from behind and exposing the bone wall of the external auditory meatus, a portion of which is removed if necessary.

Animal Parasites.—Apart from foreign bodies, the following animals have been found parasitic in the external auditory meatus: *Cheyletidæ : C. heyletus, C. eruditus* Schrank, 1781. *Tyroglyphidæ : Rhizoglyphus parasiticus* Dalgetty, 1901. *Demodicidæ : Demodex folliculorum* Simon, 1842. Larvæ belonging to the Anthomyidæ, to *Sarcophaga carnaria* Linnæus, 1758, to *Wohlfartia magnifica* Schiner, 1862, and to *Chrysomyia macellaria* Fabricius, 1794.

Otomycosis.—Otitis externa parasitica, or otomycosis, is fairly common in the tropics, and is due to a number of fungi, among which may be mentioned: *Mucor pusillus* Lindt, 1886; *Lichtheimia corymbifera* Cohn. 1884; *Lichtheimia ramosa* Lindt, 1886 (these cause otomucormycosis); *Saccharomyces ellipsoides* Rhees, 1870; *Monilia rhoi* Castellani, 1909; *Aspergillus fumigatus* Fresenius, 1775; *Aspergillus niger* von Tieghem, 1867; *Aspergillus flavus* De Bary, 1870; *Aspergillus malignus* Lindt, 1889; *Aspergilius repens* De Bary, 1870 (these cause otomycosis aspergillina).

These fungi cause mild inflammations of the external auditory meatus, and are found not merely in natives, but also in Europeans

If they grow superficially, they cause no symptoms; but if they penetrate into the mucous membrane, they give rise to itching, and sometimes to pain. If they grow into the cerumen, they may give rise to blocking of the passage, and cause tinnitus aurium and deafness.

On inspecting the ear, it will be seen that the wall of the auditory meatus is covered with a white or black macerated mucosa. The diagnosis can be made by microscopical examination, and, if necessary, by cultivation. The treatment is to syringe with a watery solution of peroxide of hydrogen, or peroxide solution (2 parts) and alcohol (1 part) once or twice a day, followed by the insufflation of boracic powder, or, if there is eczema, some boracic ointment. Damond recommends injecting a few drops of a dilute solution of sodium iodide, followed by the injection of the same amount of 12 volumes hydrogen peroxide.

Hypersecretion.—Excessive secretion of the products of the ceruminous and sebaceous glands of the external auditory meatus is common in the tropics, and is probably induced by some hyperæmia, perhaps in part du[illegible]o irritating [illegible] and partly to the hot, damp air. As a rule both ears are affe[illegible] giving rise to a sensation of fulness and heavin[illegible] in head [illegible] ion in hearing, and tinnitus aurium, and more rarely to autophony while pain is rare, though neuralgia may occur, and reflex coughing. The diagnosis is easily made by seeing the brownish-red or black mass filling up the meatus.

If the plug is soft, it can easily be removed by warm syringing; if hard, it requires to be softened by a warm solution of bicarbonate of soda (20 grains to 1 ounce of water) or glycerine of borax, and then to be removed by syringing. If deafness persists after the cerumen has been removed, it is necessary to inflate the middle ear by a Politzer's bag, which must be used with care.

Otitis Externa Circumscripta. Boils due to the entrance of pyogenic germs into a sebaceous gland or hair-follicle are not rare. They usually cause much pain, which is aggravated by moving the jaw or touching the auricle, and may cause toothache, salivation, and vertigo.

The treatment should be to relieve pain by cocaine, and the meatus should be lightly packed with gauze soaked in weak carbolic lotion. Later an incision may be made into the boil with a Dundas Grant's furuncle knife, and the meatus dressed with carbolized, glycerine on gauze. To relieve the irritable condition of the meatus, which often persists after the boil has been relieved; a little cocaine or boracic ointment combined with lanoline may be applied, and a general tonic prescribed.

Otitis Externa Ossificans.—Müller has described a diffuse inflammation of the mucosa of the external auditory meatus in the tropics which often invades the periosteum and leads to ossification, and may cause exostosis.

Deaf and Dumb.

The number of deaf and dumb people is relatively high in certain parts of the tropics—*e.g.*, in Ceylon there are 9 deaf and dumb males and 7 females out of 10,000 persons of each sex. In India there are 6 males and 4 females out of 10,000 persons of each sex. There is a deaf and dumb school in Ceylon.

Ménière's Disease.

This disease, which is characterized by severe tinnitus, and vertigo is often met with in the tropics. It occurs especially in planters, who are exposed to the midday sun. The patients frequently recover on their return to the Temperate Zone. Large doses of bromides are useful.

EAR COMPLICATIONS OF TROPICAL DISEASES.

Leprosy.

The lobules of the ear are especially liable to be attacked in tubercular leprosy, and are usually left long and thickened when the disease has abated.

Quinine.

The prolonged or considerable use of quinine may cause simple hyperæmia of the labyrinth, and may be associated with middle-ear congestion, as described by Kirchner. The symptoms are usually tinnitus aurium and deafness. It is bilateral, and comes on gradually. The quinine should be stopped, and bromide of ammonium prescribed, and afterwards euquinine, associated with bromides, may be administered.

Arsenic.

A native treatment for ear disease in the Dutch East Indies is by the application of a powder, Warangangpulver, containing some 90 to 96 per cent. of arsenious acid. According to Benjamins, this may lead to destruction of the auricle and obliteration of the external auditory meatus, with sometimes necrosis of the bone, and even fatal hæmorrhage from the internal carotid artery.

Malaria.

Reports of suppurative otitis media being caused by malaria cannot be accepted as proven, but intermittent otalgia, intermittent attacks of deafness, and labyrinthine vertigo may be of malarial origin, especially if relieved by quinine.

DISEASES OF THE NOSE.

Disease of the nose is intimately connected with disease of the ear, and to a less degree with disease of the conjunctiva. The acute catarrhal rhinitis, or common cold, may be induced by prolonged exposure to the sun's rays, as well as to chills, and is in every case an infection, though it is difficult to determine the actual micro-organism causing the disease. The commonest organism is the *Micrococcus catarrhalis*. The tropical affections, are, however, described in Chapter LXXXI., p. 1875.

Cosmopolitan Diseases.

CHAPTER XCI

PYOGENIC DERMAL INFECTIONS

Preliminary remarks—Pyogenic infections—The pyoses—The pyogenic folliculites—The pyogenic dermatites—References.

PRELIMINARY REMARKS.

In this chapter we begin a brief review of the more important skin diseases of the tropics. As this Manual is not a work on skin diseases, but is intended for the tropical practitioner, we have arranged these disorders from the standpoint of the practical physician, and have avoided a scientific classification. The chapters include pyogenic infections; fungal diseases, with the mycetomas considered separately; the dermatites due to plants; ulcers; the dermatites caused by animals; disorders of sweating and of nutrition; and miscellaneous and cosmopolitan diseases.

PYOGENIC INFECTIONS.

The skin diseases which we gather together under this heading are all caused by the pyogenic cocci, and may be distinguished as follows:—

A. Skin between the primary lesions not inflamed:—
  I. Non follicular—*The Pyoses.*
  II. Follicular—*The Folliculites.*
B. Skin primarily inflamed—*The Pyogenic Dermatites.*

THE PYOSES.

Definition.—A pyosis is a non-follicular dermal infection characterized by the appearance, on apparently healthy skin, of vesicles or bullæ, the contents of which rapidly become purulent. It is not associated with general symptoms, except slight fever in the early stages at times, and is due to the action of pyogenic micrococci.

Remarks.—The type of this variety of dermal affections is '*Pyosis mansoni,*' named in honour of Sir Patrick Manson, G.C.M.G.

Varieties.—A number of 'pyoses' are known to exist in the tropics, and these may be differentiated from one another as follows:—

A. *Primary lesions usually small* :—
  I. Situate typically in axillary and crural regions, without crusty lesions—*Pyosis mansoni.*
  II. Situate on arms and legs, with thick crusty lesions—*Pyosis tropica.*
  III. Situate on palms; rare; no crusty lesions—*Pyosis palmaris.*
B. *Primary lesions usually large* :—
  I. Typically bullæ without bright yellow crusts—*Pyosis corletti.*
  II. Typically large vesicles forming circular bright yellow crusts—*Pyosis discoides.*

Pyosis Mansoni.

Synonym.—Pemphigus contagiosus (Manson).

Definition.—Pyosis mansoni is a pyosis with primary lesions, usually small, but mixed with bullæ and affecting the axillary and scroto-crural regions. It is very common in the damp regions of the tropics.

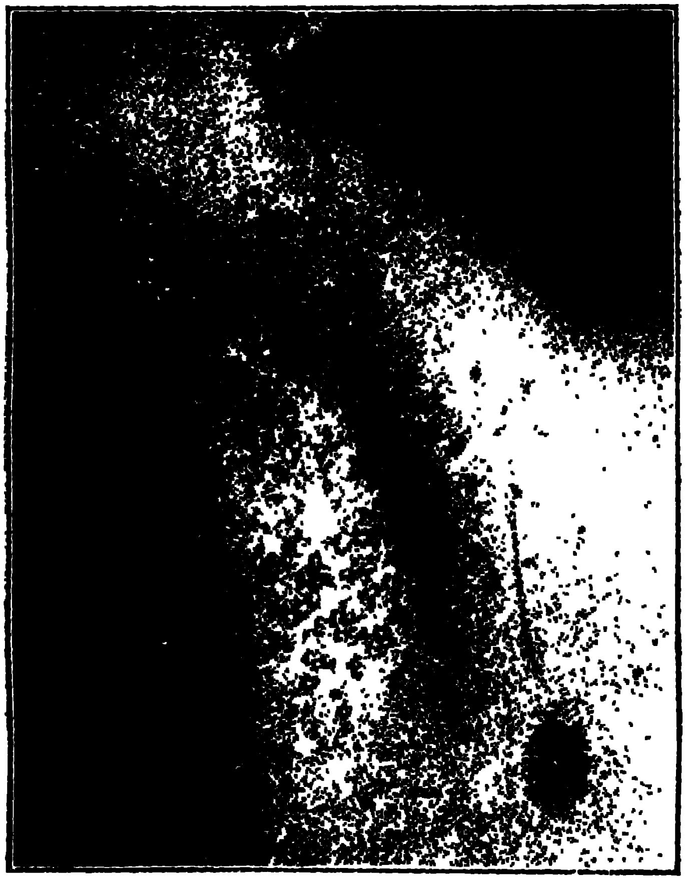

FIG. 794.—PYOSIS MANSONI.

Historical and Geographical.—This dermatosis was first described by Manson under the term pemphigus contagiosus. It is very common during the hot season in China, the Malay Peninsula, Ceylon, and Southern India, and probably in many other parts of the tropics. Castor has reported it from Burma. Very often epidemics occur among the crews of men-of-war stationed in the tropics, as observed by Clayton, or in offices, as observed by ourselves.

Ætiology.—Manson found a diplococcus; other observers have described Leishmania-like bodies; in Clayton's and our experience the examination of the contents of the vesicles shows the presence of cocci generally arranged in pairs, and having often a gonococcus-like shape. They are, however, Gram-positive, and in cultures present all the characters of the *Aurococcus aureus* and *albus*. The disease is probably spread by contact.

FIG. 794A.—PYOSIS MANSONI.
Same case as Fig. 794, but more magnified.

Symptomatology.—The affection has nothing to do with that group of diseases to which writers on dermatology apply the term 'pemphigus,' for it is much more closely related to impetigo, of which we consider it to be a variety. The eruption attacks generally the axilla, the inguinal and crural regions, from whence it often extends to the abdomen and back and limbs, rarely affecting the face. It is extremely contagious, and is generally more severe in individuals who perspire profusely and suffer from prickly heat. The eruption is made up of flattened, roundish vesicles, which quickly enlarge to the size of a small pea. Very large, flabby, pemphigoid bullae may occur, but not very frequently. The contents are at first transparent, but soon become turbid. The vesicles are often surrounded by a pinkish or reddish inflammatory halo. On being pricked, the vesicle collapses. The eruption does not usually affect the general health, but may be very persistent, and may be followed by crops of boils. As soon as the patient goes to the hills or to a cool climate it disappears spontaneously.

That the malady is merely a type of pyosis or impetigo due to the usual pyogenic cocci is shown by some cases presenting the typical bullae on the axillary regions, and soon after or though rarely at the same time boils on the arms and legs and impetiginoid lesions on the face.

Diagnosis. This is generally easy, the only difficulty being with chicken-pox. The absence of fever and the situation of the vesicles, which in pyosis mansoni usually appear in the crural or the axillary regions, however, should be sufficient to exclude this. The absence of crusty lesions differentiates the disease from the common type of impetigo contagiosa.

Prognosis. The eruption is very persistent, but does not affect the general health, except when complications such as boils develop.

Treatment. In severe cases treatment by an autogenous vaccine may be tried. Locally the affected regions should be disinfected regularly twice daily with a solution of perchloride of mercury (1 in 2,000), carbolic acid (2 per cent.), permanganate of potash (1 in 4,000), hydrogen peroxide (10 per cent.), cyllin (1 in 300), lysol or lysoform (2 to 5 per cent.). After this the vesicles are pricked, and the parts again washed with the disinfectant, an antiseptic powder being then thickly applied, such as:—

Acidi borici (finely

Europhen
Talci ven.

Dermatol
Talci ven

In some patients an ointment (europhen, 2 per cent.; protargol, 5 per cent.) answers better; the protargol ointment should never be used for the face in Europeans, as it discolours the skin after a time. It may be noted that in our experience the white precipitate ointment (1 per cent.), which is so efficacious in the usual impetigo of the Temperate Zones, has very little or no effect in pyosis mansoni. After the eruption has disappeared, it is advisable to use some Condy's fluid or other disinfectant in the bath to prevent relapses; and, if the skin is not too tender, a formalin soap may be regularly used. The underclothing should be regularly dusted with one of the above powders.

Pyosis Tropica.

Synonym.—Pyosis Castellanii, Kurunegala ulcers, Pyosis Caffra.

Definition.—Pyosis tropica is characterized by the presence of numerous crusty lesions on the legs and arms, caused by pyococci.

Historical.—Under the name 'pyosis tropica' Castellani described in 1909 a skin disease very common in Ceylon and Southern India. In Ceylon it is called by the natives Kurunegala sore, as it is especially common in that district. Pyosis tropica has been reported from other tropical countries. It has been observed, in 1912, in Tripoli by Gabbi and Sabella; in the Anglo-Egyptian Sudan by Chalmers and O'Farrell, in 1913; in South Africa by Ricono, in 1916; and by Pijper in 1918.

Ætiology. The disease is probably due to the usual pyogenic cocci, and is allied to the ordinary impetiginous and ecthymatous conditions, though much more severe. Chalmers and O'Farrell grew an organism from their case which, differing somewhat from the other species of aurococcus, was called by them *Aurococcus tropicus*. It was held to be causal because a vaccine made from it rapidly cured the case, but had no effect on a case of Nile boils; but in other cases other varieties of pyogenic cocci may be causal.

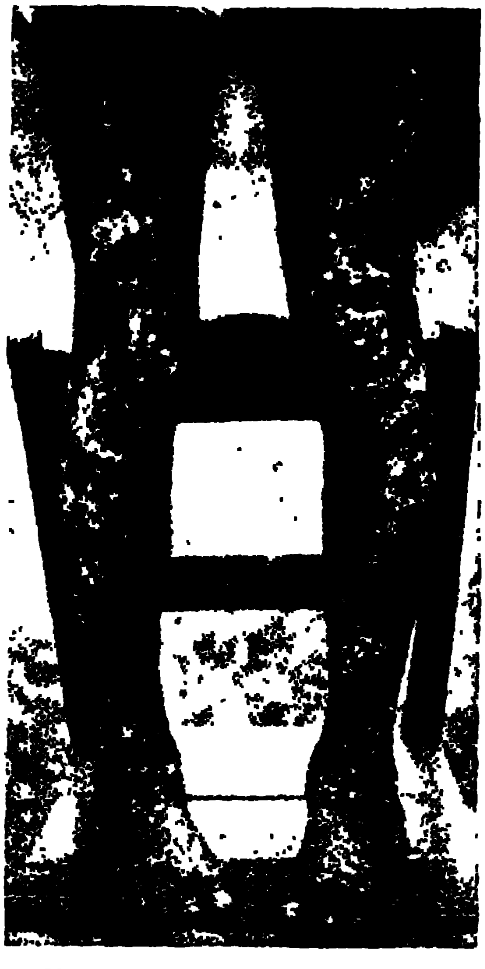

FIG. 795.—PYOSIS TROPICA.
The white patches are in reality thick yellow crusts.

Symptomatology.—The patient, generally a young boy or girl, though adults may also suffer from it, presents on the legs, arms, and occasionally all over the body, except the face, numerous crusty lesions, occasionally rupia-like, of a dirty blackish or yellowish colour. If the thick crust is removed, a shallow ulcer with an irregular margin and granulating fundus will be seen, or a small, flattened, or hemispheric nodule the size of a pea, with a pinkish, smooth surface. Besides these large lesions, small papulo-vesicles and minute pustules are often present. The larger lesions are frequently surrounded by a halo of hyperpigmentation. There is severe pruritus. On healing, also, the ulcers and nodules leave a zone of hyperpigmentation or, more rarely, depigmentation. In chronic cases plaques of hyperkeratosis may develop, especially on the exterior regions of the arms and the elbows.

Diagnosis.—On superficial examination, the disease might be easily mistaken for framboesia. In contrast to framboesia, the ulcers are superficial, and the nodules, when present, are generally smaller, have no moriform surface, and in scrapings from the lesions the *Treponema pertenue* Castellani is absent. From scabies it is distinguished by the absence of burrows and absence of the *Acarus*. From ecthyma, to which it is closely related, the condition differs by the fact that, on removing the crusts, besides the ulcerative lesions, rather large, smooth hemispheric nodules may be seen.

Prognosis.—The disease is very persistent, but the general health is not affected.

Treatment.—If the disease is not properly treated, it has a tendency to become chronic. In some cases the opsonic treatment gives satisfactory results. The vaccine should be prepared with staphylococci grown from the lesions. It has been used by Castellani with good results in Ceylon in 1910, by Chalmers and O'Farrell in 1913, and by Pijper in 1918. Chalmers and O'Farrell gave with success 250 millions of an autogenous vaccine to an adult, and repeated it in three days: Pijper treated children with 4 to 5 millions of an autogenous streptococcus obtained from a case, or by a mixture of streptococci and staphylococci. The local treatment consists in removing the crusts by soaking them with a salicylic oil made according to the following formula:—

Acidi salicylici	gr. xxx.
Olei ricini	q.s.
Olei olivæ	ad ℥iv.

or by compresses soaked in hot boric lotion.

All the lesions are then disinfected with a solution of perchloride of mercury (1 in 1,000), carbolic acid (2 per cent.), cyllin (1 in 300) or permanganate of potash (1 in 4,000). A slightly antiseptic ointment is then applied, such as europhen (2 per cent.), iodoform (2 per cent.), protargol (5 per cent.), calomel (5 to 10 per cent.). An ointment which in our experience is often efficacious is β-naphthol gr. ii.-v., acidi carbolici gr. v.-x., vaselini ad ℥i.

Pyosis Palmaris.

Definition.—Pyosis palmaris is characterized by the presence of numerous, discrete, conical, white pustules, which do not form crusts and which appear on the palms of the hands of native children.

Historical.—The disease was described some ten years ago by Castellani in native children in Ceylon, where it is rare.

Climatology.—So far it has only been recorded in Ceylon.

Ætiology.—Pyococci are present in the lesions, but may not be the true cause.

Symptomatology.—With little or no pruritus, discrete, conical, solitary pustules appear on the palms of the hands. These pustules do not coalesce or form crusts, and are not surrounded by a zone of hyperæmia.

Diagnosis.—It is distinguished from scabies by the absence of the acarus, from ringworm by the absence of a fungus, and from syphilis by the uselessness of the specific treatment.

Treatment.—Vaccines may be tried.

Pyosis Corletti.

Synonyms.—Impetigo bullosa, Impetigo contagiosa bullosa of Corlett.

Definition.—Pyosis corletti is an acute, contagious, bullous pyosis beginning on any region of the body, and characterized by the presence of medium-sized and large bullæ arising on seemingly healthy skin, and caused by *Aurococcus mollis* (Dyar, 1895).

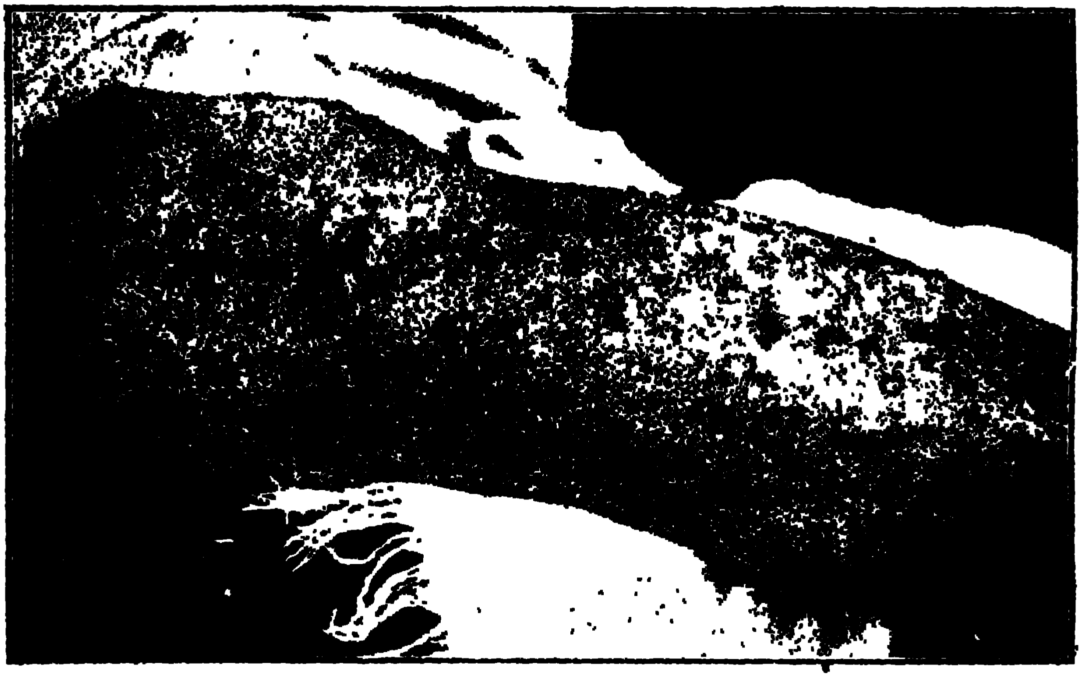

FIG. 796.—PYOSIS CORLETTI.

Historical.—In 1899 Corlett described a contagious bullous eruption as being endemic in Florida; later Singh in India invited attention to a similar disease. In 1912 Reguzis described an epidemic among Europeans in Cairo. In 1915 Chalmers and O'Connor gave a description of an epidemic of this disease as seen in the 1st Battalion of the Suffolk Regiment in Khartoum.

Ætiology.—The causal organism so far found is *Aurococcus mollis* (Dyar, 1895). It is causal because (1) it is the only organism present, and is found in the youngest vesicles: (2) it was obtainable from all the cases of the Khartoum epidemic, and a similar organism was found by Corlett, but not fully defined; (3) a vaccine prepared from it cured the patients quickly. It is, of course, possible that the same clinical correlation may be caused by various, as yet unknown, allied organisms.

The Khartoum epidemic was traceable to a case of 'Nile boils,' caused by the same organism.

Symptomatology.—The incubation period is unknown, but in some cases the initial lesion is a small papule on the head or chest, which is so quickly followed by an outbreak of bullæ that the eruption is well developed in two days.

The essential feature of the eruption is a bulla arising on apparently healthy skin, and measuring about 2 cm. in diameter, but associated with some much larger blebs measuring about twice this size, and also smaller bullæ which rapidly increase in diameter.

A bulla appears to start as a small vesicle situate in the epidermis, containing a clear, watery fluid. This vesicle rapidly increases in size until it forms a bulla, the walls of which are, first tense and the contents watery, but later they become flaccid and the contents purulent.

The bulla bursts, the contents escape, and the lesions dry up and disappear, usually without forming a scab, but in the case of the larger lesions it leaves behind it a certain amount of dark discoloration of the skin, indicating the affected area.

If a bulla is pricked it is found to have a glazed, parchment-like base. The edges of the bulla are also observed to be undermined, and it is apparent that the increase in size from a vesicle or small bulla to a larger one is by the spreading outwards of the edges. If scratched, excoriations and crusts are formed, but crusty lesions are rare and, when present, only slightly developed.

The bullæ are situate most abundantly on the thighs, back, and chest, and less abundantly on the neck, arms, and legs, and more rarely on the face and head. The axillary and scroto-crural regions are singularly free from the disease, only one case showing a slight amount of the eruption at the margins of the axillæ.

There are no constitutional symptoms, and only rarely do cases complain of a slight amount of itching, which is probably due not so much to the eruption itself as to the rubbing of the clothing producing slightly raw areas where bullæ have burst. When this takes place, small scabs are apt to form, especially if the patient scratches the area, but they are entirely secondary in nature and not part of the true eruption.

The differential leucocyte count based on 1,000 cells is:—

Polymorphonuclear leucocytes	86·7
Mononuclear leucocytes	3·8
Large lymphocytes	4·4
Small lymphocytes	3·2
Eosinophile leucocytes	1·9
Total	100·0

Diagnosis.—The important diagnostic characters of the eruption are the absence of constitutional disturbance, the absence of severe itching, the presence of relatively large bullæ arising from apparently sound skin and not surrounded by inflamed areolæ, the absence of marked incidence on the axillary and scroto-crural regions, the absence of crusts and of streptococci, the presence of *Aurococcus mollis*, and finally the ready reaction to treatment by a vaccine prepared from this organism.

Differential Diagnosis.– The differential diagnosis must be made from impetigo contagiosa, dermatitis bullosa plantaris, pemphigus acutus, and pyosis mansoni.

It can readily be differentiated from impetigo contagiosa by the absence of crusty lesions as a rule, and by the fact that even when the youngest vesicle is examined by Sabouraud's methods no streptococcus can be found and only *Aurococcus mollis* (Dyar).

From dermatitis bullosa plantaris it may be distinguished by not attacking the soles of the feet as far as has been recorded, by not extending between the toes, and by the absence of streptococci and *Epidermophyton cruris* Castellani.

From pemphigus acutus it can be recognized by the absence of the severe constitutional disturbance.

From pyosis mansoni it can be differentiated by the fact that it does not begin in the axillæ or scroto-crural regions, and that it but rarely, and then lightly, attacks those parts which are the primary seat of Manson's pyosis.

The principal feature of the eruption in Manson's disease is flattened, roundish vesicles which enlarge to the size of a small pea, while large, flabby, pemphigoid bullæ are rare; but in this eruption large pemphigoid bullæ are common. In Manson's pyosis the vesicles are often surrounded by a pinkish or reddish inflammatory halo, which is absent in the present eruption.

Complication. Eruptions of boils may occur.

Sequela.—When cases are not treated by vaccine therapy there appears to be a liability to boils as a sequela.

Prognosis.—The prognosis is excellent, as the disease is rapidly cured by a combination of vaccine and local therapy.

Treatment.—The best form of treatment is to prepare a vaccine which is to be administered in 200 and 450 million doses, with intervals of two to three days between each dose.

In order to expedite the cure local treatment is also useful, and this consists in pricking each blister and catching the exuding fluid on swabs dipped in 1 in 1,000 lotio hydrargyri perchloridi.

After pricking, each blister should be thoroughly disinfected with the same lotion, and be dusted with some antiseptic powder, the cheapest, but not the best, being boric acid, while the same with starch should be used for dusting the clothing in order to attempt to prevent the spread of the infection.

A vaccine prepared from a case of Pyosis corletti acts also generally on cases of Nile boils, and *vice versa*. This is easily understood, as the two conditions are due to the same organism—*Aurococcus mollis* (Dyar).

Prophylaxis.—The important points in the prophylaxis are to realize that the disease may originate from a case of boils, may cause no symptoms, and may be overlooked.

Pyosis Discoides.

Definition.—Pyosis discoides begins as a generalized vesicular eruption of fairly large roundish vesicles, which rapidly become purulent and then dry, forming circular, discoidal, bright yellow crusts surrounded by a slightly hyperæmic zone and associated with pyogenic cocci, and in the early stages often accompanied by slight fever.

Historical.- This eruption was found by Castellani in 1914, in a man in Ceylon, and again in the Balkans.

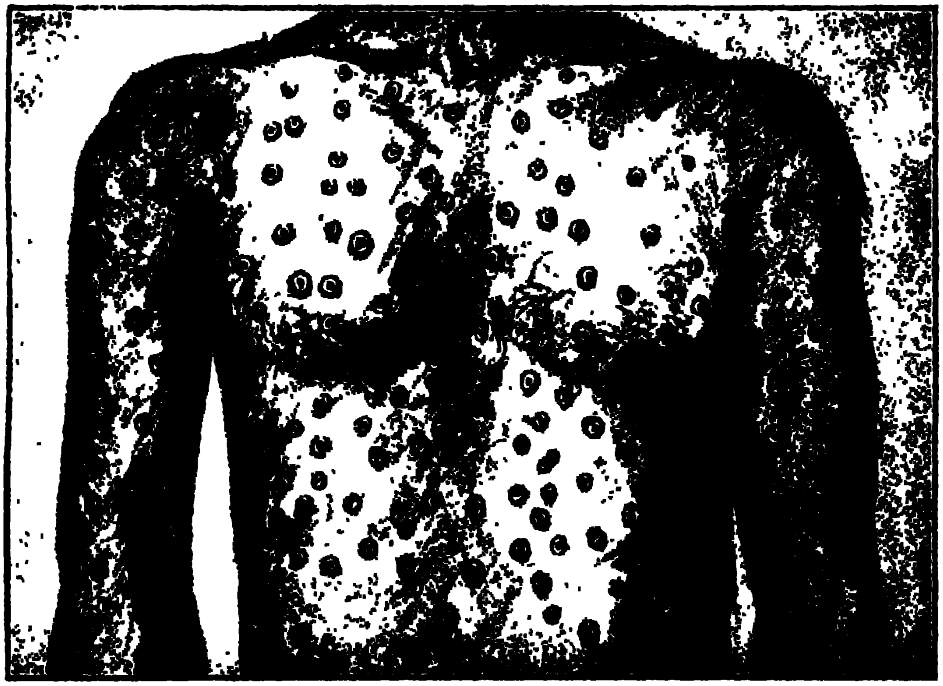

FIG 797.—PYOSIS DISCOIDES.
(From a rough sketch made by an Austrian prisoner in Macedonia.)

Ætiology.—Streptococci and staphylococci have been found in the lesions.

Symptomatology.—The symptoms may be discussed in two stages:—

Vesicular Stage.—There is a profuse generalized eruption of fairly large roundish vesicles, some of which are flaccid.

Stage of Discoidal Crusts.—The contents of the vesicles are at first clear, but soon become purulent, and then dry up, forming circular, discoidal, bright yellow crusts, firmly embedded in the deeper layers of the epidermis, and often surrounded by a hyperæmic halo. When these firmly fixed crusts are removed, shallow circular ulcers with sharply defined edges are produced.

General Symptoms.—Constitutional symptoms are of the slightest, but during the first few days of the eruption there may be slight fever.

Diagnosis.—The definition indicates the principal characters of the complaint. As regards the differential diagnosis, this must be made from chicken-pox, in which the bright yellow, discoidal, deeply attached crusts are absent.

Treatment.—The treatment advised is 1 per cent. white precipitate ointment.

THE PYOGENIC FOLLICULITES.

These are pyogenic affections of the hair follicles caused by cocci. The following varieties may be differentiated:—

A. Deep-seated in the hair follicle; occur anywhere—*Tropical boils.*

B. Superficially situate in the hair follicle; found on the legs and thighs—*Purulent folliculitis of the legs.*

Tropical Boils.

Synonyms.—Tropical furunculosis, Nile boils, Mango boils.

Definition.—A tropical boil is a deep-seated purulent inflammation of a hair follicle due to pyococci.

Remarks.—Furunculosis is very common in the tropics. It does not differ from what one sees in Europe except that it is often of much severer type, and has a great tendency to spread all over the body. The individual boils are frequently of very large dimensions and extremely painful. There may be fever. The condition is very common in people who perspire much and suffer from prickly heat.

Ætiology.—It is due to staphylococci. Carbuncle, especially of the neck and gluteal regions, with deep infiltration and multiple openings, is not rarely associated in our experience with ordinary boils. The so-called 'Nile boils' have been examined bacteriologically by Chalmers and Marshall and by Archibald, and have been shown to be generally caused by *Aurococcus mollis* (Dyar, 1895).

E. Black describes under the term 'furunculus contagiosus' a benign multiple furunculosis observed by him in Brazil.

Treatment.—The quickest and most reliable method of cure in cases of multiple boils is, in our experience, Wright's vaccine treatment, the vaccine being prepared from staphylococci isolated from the patient, or being prepared from organisms known to occur in a given district. When this treatment cannot be carried out, the administration of fresh yeast, half a wine-glassful twice daily, or of yeast preparations internally, will be found to be useful in some cases—*e.g.*, two or three ceridin pills twice daily. Ichthyol tablets (gr. v.), twice daily, may also be given, or calcium sulphide (gr. ¼) may be administered, but their beneficial effect is doubtful. Diluted sulphuric acid (♏ xx.-xxx.), well diluted, every four hours may be tried. Occasionally a small boil may be aborted by applying a droplet of pure carbolic acid by means of a pointed pencil of wood drilled into the centre of the papule, or four or five drops of 1 in 30 solution of carbolic acid may be injected beneath the boil, or Unna's carbolic and mercury plaster may be used, or spirit of camphor may be applied several times daily. For old indurated boils the continuous application of a carbolic lotion (2 to 5 per cent.) on lint occasionally causes them to become absorbed. Large boils in which suppuration has taken place should be opened, but it is a mistake to open them too soon. As a preventive, a salicylic-alcoholic lotion (1 to 2 per cent.), used after the daily bath, is advantageous, and it is also advisable to use a little Condy's fluid or cyllin in the bath.

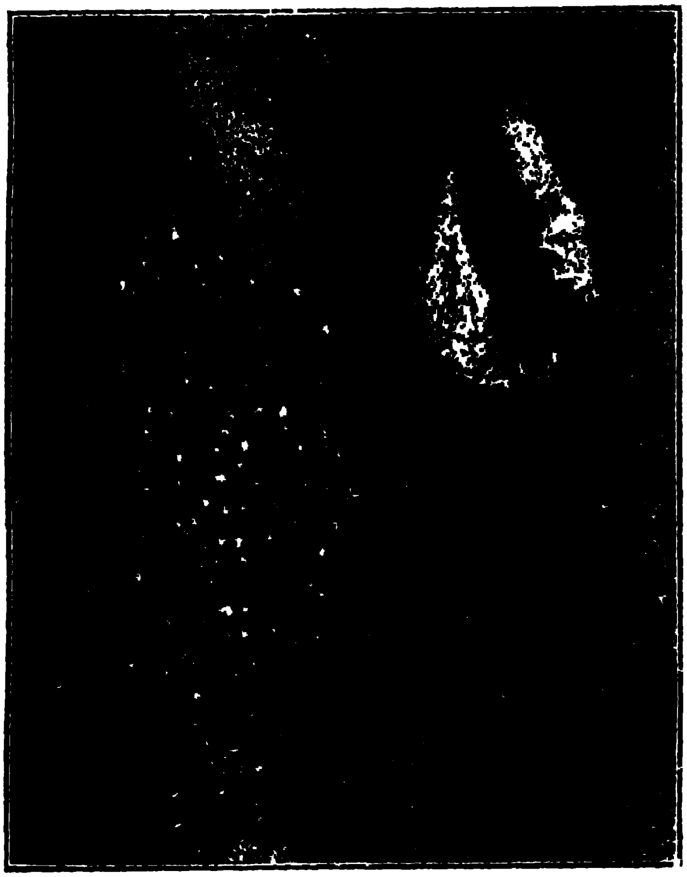

FIG. 798.—PURULENT FOLLICULITIS OF THE LEGS AND THIGHS.

Stanoxyl by the mouth only is not satisfactory, but is said to give good results when administered in baths.

Purulent Folliculitis of the Legs.

Definition.—A purulent inflammation attacking many hair follicles of the legs and thighs.

Historical and Geographical.—The condition is extremely common in Ceylon and Southern India, in the former especially among the moormen. It was investigated by Castellani some years ago. A very similar or identical condition has been noted by R. Cranston Low in Scotland in miners working in mines flooded with water.

Ætiology.—It is apparently due to the usual pyogenic cocci.

Symptomatology.—The patient presents on his legs—especially the extensor region—numerous whitish conical pustules. Each pustule is pierced by a hair. The pustules remain, as a rule, separate, do not increase in size to any extent, and do not coalesce nor form crusty lesions. After a time the skin of the legs may show a peculiar parchment-like appearance. The examination of the pus contained in the pustules shows the presence of the ordinary staphylococci.

Prognosis.—The disease, if left untreated, runs a very long course.

Treatment.—The treatment consists in depilation, application of antiseptic dressings, and, later, the application of an antiseptic ointment or paste. In obstinate cases the opsonic treatment, carried out with a vaccine prepared from the staphylococci grown from the lesions, gives good results. The following ichthyol application may be found useful: Ichthyol, 2 drachms; glycerine, 1 drachm; distilled water to 1 ounce.

THE PYOGENIC DERMATITES.

Definition.—The pyogenic dermatites are inflammations predominantly of the surface of the skin, which are caused by the pyococci.

Remarks.—The old term eczema was introduced by Ætius of Amida, in the sixth century A.D., for the breaking out of burning, itching, non-ulcerating vesicles, and was used by Willan for an eruption of minute vesicles, non contagious, closely crowded together, forming thin flakes and crusts when the fluid they contain is absorbed, and due to *irritation* whether *internally* or *externally* applied. The causes which Willan had in mind were mercury applied internally and the rays of the sun externally.

After years of confusion the modern tendency is to consider that the word 'eczema' is a cloak for ignorance.

In lieu of it the word 'dermatitis' may be employed, if by this is meant an inflammation predominantly of the surface of the skin. So defined, dermatitis may be classified into:—

1. Dermatitis due to chemical causes.
2. Dermatitis due to physical causes.
3. Dermatitis due to parasites.

The term eczema should only be used when the practitioner is unable to assign its proper cause to a dermatitis. The term is therefore a cloak for ignorance of the causation of the dermal condition.

In the present section we are considering a part of the third class of dermatites—viz., those due to parasites—and in particular that subclass which is brought about by the pyococci.

We, however, propose to further restrict our remarks to merely the streptococcal dermatites, and will consider them under two headings—viz.:—

Primary Streptococcal Dermatites.
Secondary Streptococcal Dermatites.

THE PRIMARY STREPTOCOCCAL DERMATITES.

Definition.—A primary streptococcal dermatitis is an inflammation predominantly of the surface of the skin, localized or generalized, and caused by streptococci.

Remarks.—Streptococci appear to have been first observed in cutaneous lesions by Crocker in 1881, and to have been later identified by Brockhart as *Streptococcus erysipelatosus* Fehleisen, 1883. Later they were carefully described by Whitfield, Colcott Fox, and many other observers, including ourselves. Colcott Fox classified streptococcal skin lesions with those which occur in the course of grave systemic affections, those which are lesions of the hypoderm, those which are primary, and those which are secondary cutaneous lesions.

With regard to the primary streptococcal dermatites, these are sufficiently numerous, but for our present purpose we will restrict our attention to those found in the tropics, which are *dermatitis veldis*, *dermatitis pratensis*, and *dermatitis cupoliformis*, which may be distinguished from one another as follows:—

A. *Nodules not produced*:—
  I. Begins as a large blister or bulla, and forms a superficial sore with ragged edges, and a fresh clean floor in recent, or a parchment-like floor in old cases—*Dermatitis veldis*.
  II. Begins as a small irritable papule or papulo-vesicle, which ulcerates, glazes over, spreads, and finally gives rise to an area defined by a raised margin, inside which are deep fissures and ulcerated areas, and often in later stages papillomatous outgrowths—*Dermatitis pratensis*.

B. *Nodules produced—Dermatitis cupoliformis.*

Dermatitis Veldis.

Synonyms.—Veld sore, Barcoo rot, Gift zeer, Brand zeer.

Definition.—A primary streptococcal dermatitis characterized by the formation of a bulla, followed by a superficial sore, which becomes very chronic, but does not lead to papillary acanthotic formations.

History.—For long the Bushmen of the region known as Barcoo River, North Queensland, have suffered from sores which they call Barcoo rot. In the Transvaal the inhabitants are afflicted with a sore which they call 'gift zeer' or poison sore, while in the Free State the residents are attacked by a similar sore which they call 'brand zeer' or burn sore.

In 1901 Ogston and in 1904 Harman reported upon these conditions under the name 'veld sore,' a term used by the English settlers in South Africa. Harman further proved that it was the same as Barcoo rot by the evidence of Australian Bushmen who had suffered from the one in Australia, and from the other in South Africa recognizing them as the same. In 1913 Black gave us his personal experiences of Barcoo rot. In 1917 Martin met with a similar condition in the Anzac Mounted Division operating in the desert east of the Suez Canal, and again it was recognized by the men who had seen or experienced Barcoo rot to be the same complaint.

Climatology.—The disease is known to occur in Tropical Australia, South Africa, Egypt, and Equatorial Africa.

Ætiology.—Harman obtained staphylococci and streptococci from his cases. He was inclined to consider his yellow staphylococcus as the causal organism, and called it *Micrococcus vesicans*, but it is more probable that the causal agent is the streptococcus which may be known provisionally as *Streptococcus vesicans*, and which may be only a synonym for some more fully worked out species such as *S. versatilis* Broadhurst, 1915. The disease can be reproduced in man by inoculating the fluid of the blisters on to a raw place in the skin.

Pathological Histology.—The fresh unopened blister has been studied by Harman, who found that it occurred in the layers of the epidermis. The stratum corneum is raised, forming the roof of the blister, which begins as a cleft in the stratum lucidum. The epidermis is never wholly absent from the floor, which is composed of swollen cells of the stratum lucidum and stratum granulosum. The dermis shows a moderate degree of leucocytic invasion beneath the floor of the ulcer. Cocci in the form of diplococci or short chains are found in spaces between the cells of the epidermis.

Symptomatology.—The dermatitis begins by the patient feeling a pricking or burning sensation in some part of the body. On examining this, he finds that on the site of some small abrasion there is a little blister surrounded by a hyperæmic zone. The blister quickly increases in size until it may attain that of a shilling, but more usually it grows slowly, and when the size of a sixpenny-piece is reached it usually bursts, setting free some sero-purulent fluid and forming a superficial ulcer with a red floor and roundish or somewhat festooned margins.

The floor of the ulcer remains dry like parchment. The ulcer may be painful, but, especially at the beginning, there is frequently more itching than pain. The proximal lymphatic glands may be enlarged. Several such sores may be present at the same time. The hands, forearms, feet, and legs are mostly affected. Harman has seen as many as twenty such sores on one man. The duration of the affection varies between one and three months, but occasionally may last as long as six months.

Treatment.—The correct treatment is by vaccines, either autogenous or from a locally prepared stock. The local treatment consists in keeping the sores dressed with antiseptic lotions, such as perchloride of mercury (1 in 4,000), or in washing the sores with a disinfecting lotion, and then applying an antiseptic powder, paste, or ointment, such as europhen (1 to 3 per cent.), iodoform (1 to 3 per cent.), protargol (5 to 10 per cent.), or calomel (5 to 10 per cent.).

Barcoo Rot.

For the reasons given above we consider Barcoo rot to be a condition identical with *dermatitis veldis*. It must, however, be admitted that the descriptions given by some authors may include other conditions. For example, Black described it as forming a crust which becomes larger, thicker, and harder until horny in consistence and difficult to remove. There is very little itching or pain.

Pain states that the term ' Barcoo rot ' is very loosely applied. According to him the original ' Barcoo rot ' was scurvy. Owing to the improved conditions of living scurvy disappeared, and the younger Bushmen applied the name to any superficial obstinate sore. Two conditions at least are now covered by the term: a seasonal staphylococcal infection, occurring generally in the autumn, and a deep-seated trichophytosis of the hands.

Dermatitis Pratensis.

Definition.—Dermatitis pratensis is a primary streptococcal dermatitis characterized by starting as a papule spreading by ulceration, and forming in late stages acanthotic papillary formations.

Historical. The disease has been studied by Castellani in Equatorial Africa and by Chalmers and Archibald in the Anglo-Egyptian Sudan. We give it the name *dermatitis pratensis* to bring it into line with the other *dermatites*.

Ætiology.—The causative organism is a streptococcus which can be found in the polymorphonuclear leucocytes, in the lesions, and can easily be grown in pure culture. In some cases in the Anglo-Egyptian Sudan the organism obtained was *Streptococcus versatilis* Broadhurst, 1915, which is a normal denizen of equine fæces, from which the infection probably comes. Its causal relationship depends upon not merely its presence in cases of the disease, but upon the fact that vaccines prepared from it will quickly cure not merely the person from whom the growth was obtained, but other patients also.

Pathological Histology.—When sections are made along a papillomatous projection of the acanthotic variety it will be seen that the outer covering is epidermal in nature, and that, superficially, it is covered by masses of scales, both on its free surface and on the surface looking towards another process.

This epidermis shows the defect of cornification called 'parakeratosis' by Auspitz, while with regard to the rete there is a certain degree of acanthosis.

The corium is full of dilated vessels, and is also slightly œdematous and fairly cellular.

The cells consist of forms with a large, well-stained nucleus and a fringe of cytoplasm, which are supposed to be derived from connective tissue cells. Plasma cells and mast cells may also be seen, as may an occasional polymorphonuclear leucocyte.

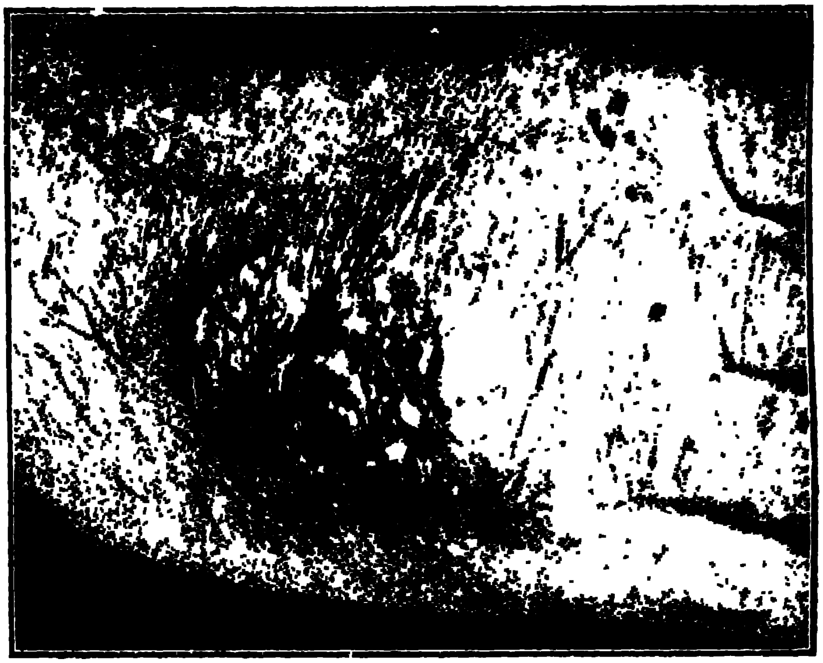

Fig. 700.—Dermatitis Pratensis.

Turning now to the non-papillomatous regions, there is a well-defined epidermis with parakeratosis and acanthosis, while the cellular infiltration of the corium is denser. It is somewhat œdematous.

Raw areas show parakeratoses, which are distinguished by the extraordinary development of the acanthosis.

In the region where the epidermis is missing all trace of a normal corium is lost superficially, and its place is taken by a fibrocellular exudate.

Embedded in this exudate can be seen the remains of the acanthotic prolongations of the epidermal cells.

In this fibrocellular mass lie numerous bloodvessels filled with corpuscles, while patches of serous exudation can also be observed.

The cells of the mass are largely composed of the same cells as in the corium of other pieces, but the amount of polymorphonuclear leucocytes in certain regions, and more especially superficially, is marked.

In the deeper part of the section isolated pieces of the ordinary connective tissue of the corium can be seen, while finally, in the depth of the section, well-defined connective tissue is seen containing here and there scattered collections of cells of the same nature, as already described for other portions of the tissue.

The sweat glands are much damaged, and surrounded by cells of the usual type found in these lesions.

Still deeper one meets with fatty tissue, between the cells of which lies an accumulation of the typical cells of the lesion.

Symptomatology.—The eruption begins as a small pruriginous papule or papulo-vesicle, which increases in size and ulcerates, scabs over, and extends at its margins. When fully developed it is surrounded by a raised margin, behind which small papillæ may be noted, which in older cases give rise to very distinct papillomatous outgrowths. The surface of the sore is composed of deep fissures and a few ulcerated areas, which exude a serous fluid, which is apt to form crusts. These ulcerated areas and fissures are separated by other areas coated by a thin epidermal covering, which gives rise to a false pealing appearance. The whole condition spreads slowly from the margin.

Diagnosis.—This is sufficiently effected by the table given on p. 2030.

Prognosis.—The prognosis is good provided that the patient is otherwise healthy.

Treatment.—The best treatment is, without doubt, an autogenous vaccine, but a polyvalent local (*i.e.*, made from local strains) vaccine acts quite well.

We generally give 10 millions to commence with, then 50, and, if necessary, 100 millions.

The affected part in chronic cases may be painted with iodine and a dry dressing applied.

Dermatitis Cupoliformis.

Synonym.—Tropical ecthyma (Castellani).

Definition.—Dermatitis cupoliformis is characterized by commencing as dusky red macules, which are follicular or perifollicular, which either disappear or slowly become cupoliform nodules, which after a time break down and ulcerate.

Historical.—This disease was first described by Castellani in 1914 as seen mostly in Europeans in Ceylon. Subsequently he met with the disease in the Balkans.

Climatology.—So far it is only reported from Ceylon and the Balkans.

Ætiology.—It is caused by a streptococcus belonging to the erysipelatous group (*vide* Chapter XXXVI., p. 929), which is named *S. tropicalis* Castellani, 1914.

Symptomatology.—The disease begins as superficial, dusky red, follicular, or perifollicular slightly itching macules on the feet and legs. Some of these spots disappear, while others become slowly larger, raised, hard, infiltrated, and cupoliform, reaching the size of a pea or a small cherry. After a time the centre of the nodule breaks down and forms an ulcer, with a reddish floor and undermined edges.

These ulcers are somewhat painful and very slow to heal, and when this does take place it produces patches of hyperpigmentation. The course of the disease is very long, lasting at times more than a year.

Diagnosis.—The characteristic features of the eruption are the presence of raised, hard, rather large cupoliform nodules, some of which show a central ulcer with undermined edges.

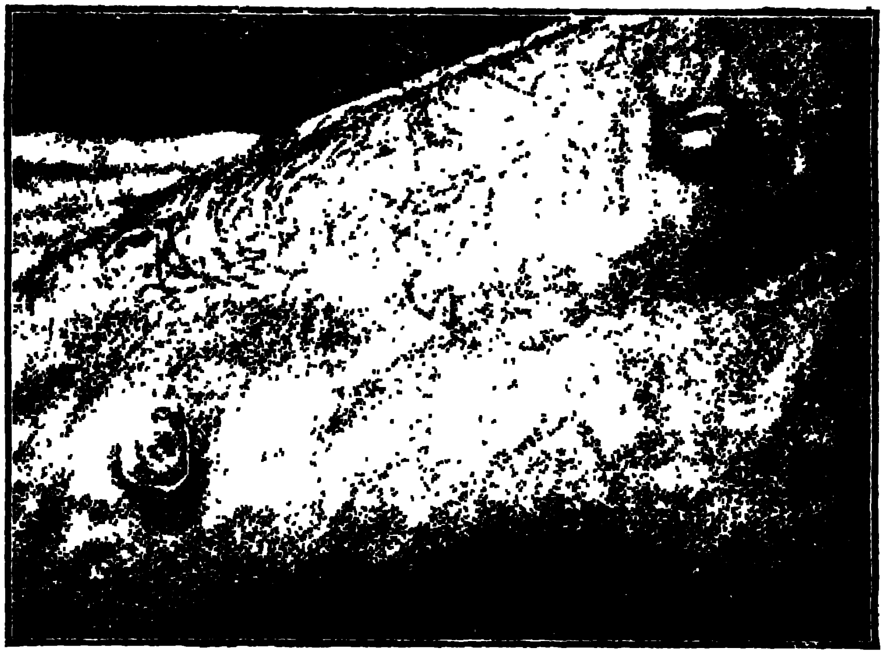

FIG. 800.—DERMATITIS CUPOLIFORMIS OF THE FOOT

The differential diagnosis has to be made from *Oriental sore* by the absence of Leishman-Donovan bodies.

From *ecthyma* it may be distinguished by the absence or rarity of the pustular lesions with a brownish crust. In ecthyma the initial lesions are always pustular, there being generally discrete flat pustules; when these rupture a brownish crust is formed beneath which suppuration goes on. In the condition known as 'ecthyma gangrenosum,' occasionally met with in cachectic children, especially during convalescence from varicella and other exanthemata, the initial lesions are vesicular or pustular, and no nodules are present.

In *pyosis tropica* the ulcers do not show undermined edges, and pustular lesions are present.

In *purulent folliculitis of the legs* there are no ulcers, only pustules pierced by hairs being present.

Prognosis.—The condition runs a very long course and is difficult to cure, unless treated by an autogenous vaccine.

Treatment.—An autogenous vaccine is the correct treatment, and generally produces a cure in two to three weeks. Local treatment by antiseptic lotions is also recommended.

THE SECONDARY STREPTOCOCCAL DERMATITES.

Only two forms of this affection concern us, and both are secondary to infections with *Epidermophyton cruris* Castellani. They are dermatitis interdigitalis and dermatitis bullosa plantaris.

They may be differing phases of the same affection, but they can be differentiated as follows:-

A. Situate primarily between the toes. Bullæ absent—*Dermatitis interdigitalis*.

B. Situate primarily on the soles. Bullæ present—*Dermatitis bullosa plantaris*.

Dermatitis Interdigitalis.

Synonyms. Dermatitis rimosa of the toes, Mango toe (Ceylon), Frieira (Brazil).

Definition.—Dermatitis interdigitalis is a streptococcal dermatitis secondary to an infection of the parts between the toes caused by *Epidermophyton cruris* Castellani.

Historical. This affection, which is popularly known in Ceylon as 'Mango toe,' was first brought into prominence by Sabouraud's observation that the primary cause was an infection by *Epidermophyton cruris* Castellani. In 1910 Castellani found that very often there was a secondary streptococcal infection.

A somewhat similar affection was described long ago by Martin Costa in Brazil, who stated that the condition was very common among natives, who called it 'frieira.' He believed it to be caused by the heavy perspiration, and accumulation of dust and dirt between the toes.

Geographical Distribution.—It is extremely common in Southern India, Burma, Ceylon, and many other tropical countries, being the cause of great discomfort to European residents, especially during the hot season.

Ætiology.—The condition seems to be a pyogenic infection, starting generally on slight lesions produced by a localization of *Epidermophyton cruris* Castellani to the toes. This localization of the fungus was first observed by Sabouraud. The fungus *per se* in this situation gives rise to very slight symptoms very often only some scaliness and pruritus.

Symptomatology.—The patient first complains of great itching between the toes, without there being present any papular or vesicular lesion. On scratching to relieve this itching, portions of the epidermis become removed, and small, superficial, red, irritable abrasions are seen. These become severer, and deep, extremely painful fissures appear between the toes in almost all the cases. This dermatitis is difficult to cure, but disappears rapidly on the patient going to the hills or to Europe. It may remain quiescent for long periods, and then reappear again. During the periods of quiescence some pruritus may occasionally be felt, and the skin between the toes may easily crack or be slightly scaly.

Treatment.—This consists in keeping the patient at rest for a few days, dressing the affected parts continuously with diluted carbolic lotion (½ per cent.), or resorcin lotion (½ to 1 per cent.), and later applying a zinc oxide paste, hazeline cream, or a bismuth boric ointment (bismuth subnitratis, gr. xxx.; acidi borici, gr. xv.; vaseline, lanoline, āā ʒiv.). The stockings should be white, and should be changed at least twice daily, and should be boiled before use. If a fungus is found in the lesions, an antimycotic treatment should be carried out when the acute stage is over, or during the quiescent periods, by means of silver nitrate (3 per cent.), or a strong solution of potassium permanganate (gr. xxx. to ℥i.), painted on once or twice daily; or tincture of iodine may be used if the lesions are dry and there are no excoriations.

Dermatitis Bullosa Plantaris.

Synonym.—Foot-tetter (Cantlie).

Definition.—Dermatitis bullosa plantaris is a streptococcal dermatitis, often secondary to an infection of the soles of the feet, caused by *Epidermophyton cruris* Castellani.

Historical and Geographical Distribution.—This affection was first described by Cantlie in China, but cases are met with in all tropical countries.

Ætiology.—The disease is probably a streptococcus infection, one of us having isolated a very virulent strain of the germ from the blebs of a number of cases. In several of our cases this streptococcus infection developed on some superficial lesions due to a localization of *Epidermophyton cruris* Castellani to the soles.

Symptomatology.—It commences with blebs on the sole of the foot. The blebs ultimately break, and by-and-by bare scaly flakes of skin form, and extend all over the sole and between the toes. There is intense itching. Occasionally the condition spreads to other parts of the body. It usually dies away in the cold season, but recommences in the hot season. According to Cantlie, patients who have returned to Europe see their affection reappearing regularly every summer for ten or twenty years after leaving the tropics.

Prognosis.—The condition is of difficult cure, and relapses occur.

Treatment.—In the acute stage the patient must stay at complete rest, and antiseptic dressings, such as mercury perchloride (1 in 4,000) or carbolic acid (½ per cent.), applied continuously. Later a lead lotion (liq. plumbi, ʒii., aq. destil. ad ℥x.), and still later some antiseptic powder (dermatol or zinc oxide) may be used. In our cases ointments were always badly borne. In mild cases we advise taking a foot-bath twice daily in warm boric (1 per cent.) or permanganate (1 in 4,000) solution, besides which the blebs should be pricked with a sterile needle and touched with a solution of permanganate (gr. xx.-xxx. to ℥i.), followed by dressing with zinc oxide, dermatol, or some similar powder.

If the eruption develops on lesions due to fungi, when the acute stage is passed off, an antimycotic treatment should be carried out by applying with care, and very little at a time, a silver nitrate solution (3 to 5 per cent.) if there are moist lesions, or tincture of iodine if the lesions are dry.

Cantlie recommends the application of pastes and plasters as palliatives. Manson advises the use of a daily foot-bath of a 2 per cent. solution of carbolic acid for half an hour.

CHAPTER XCII

TROPICAL DERMATOMYCOSES

Tropical dermatomycoses—Tinea cruris—Tinea alba—Tinea albigena—Tinea sabouraudi tropicalis—Tinea nigro circinata—Tinea capitis tropicalis—Tinea barbæ tropicalis—Tinea ciliorum—Tinea unguium tropicalis—Tinea imbricata—Tinea intersecta—Tinea flava—Tinea nigra—Erythrasma—Blastomycosis—Sporotrichosis—Cryptococcosis epidermica—Intertrigo saccharomycetica—Aspergillosis—Penicilliosis—Acladiosis—Cryptococcosis epidermica—Pinta—Piedra—Trichomycosis—Rarer nodular and gummatous affections of hyphomycetal origin—References.

TROPICAL dermatomycoses—that is so say, tropical skin diseases caused by fungi higher than bacteria—may be classified as follows:—

TROPICAL DERMATOMYCOSES

Due to fungi of the genus *Epidermophyton* Lang, 1879, *Trichophyton* Malmsten, 1845, *Microsporum* Gruby, 1843

- *E. cruris* Castellani, 1905, common variety of Tinea cruris (dhobie itch).
- *E. p. perneti* Castellani, 1907, variety of Tinea cruris.
- *E. p. rubrum* Castellani, 1909, variety of Tinea cruris.
- *T. nodoformans* Castellani, 1911, variety of Tinea cruris.
- *T. macfadyeni* Castellani, 1905, variety of Tinea alba.
- *T. albiscicans* Nieuwenhuis, 1907, Tinea albigena.
- *T. blanchardi* Castellani, 1905, Tinea sabouraudi tropicalis.
- *T. ceylonense* Castellani, 1908, Tinea nigrocircinata.
- Varieties of Tinea capitis.
  - *T. soudanense* Joyeux, 1912
  - *T. violaceum* Bodin, 1902
  - *T. violaceum* Bodin, 1902, var. *decalvans* Castellani, 1911
  - *T. currii* Chalmers and Marshall, 1914
  - *T. discoides* Sabouraud, 1909
  - *T. violaceum* Bodin, 1902, var. *khartoumense* Chalmers and Macdonald, 1915
  - *T. polygonum* Uriburú, 1909
  - *T. exsiccatum* Uriburú, 1909
- *Microsporum flavescens* P. Horta, 1912, variety of Tinea capitis and corporis.

II. Due to fungi of the genus *Endodermophyton* Castellani, 1909

- *En. tropicale* Castellani, 1914. Tinea imbricata.
- *En. indicum* Castellani, 1911, Tinea imbricata.
- *En. castellanii* Perry, 1907, Tinea intersecta.

III. Due to fungi of the genus *Malassezia* Baillon, 1889	*M. tropica* Castellani, 1905, Tinea flava.	
IV. Due to fungi of the genus *Cladosporium* Link, 1809	*C. mansoni* Castellani, 1905, Tinea nigra. *C. madagascariense* Verdun, 1913, peculiar nodular affection.	
V. Due to fungi of the genera *Saccharomyces* Meyen, 1838, *Cryptococcus* Kützing, *Coccidioides* Rixford and Gilchrist, 1897, *Monilia* Persoon, 1797	Several species, some of which incompletely investigated	Varieties of blastomycosis.
VI. Due to fungi of the genus *Nocardia sensù lato*, Toni and Trevisan, 1880, and *Cohnistreptothrix* Pinoy 1911	*N. minutissima* Burchardt, 1859, erythrasma. *N. carougeaui* Brumpt, 1910, juxta articular nodules. *N. rieurei* Verdun, 1912, nodular affection. *C. tenuis* Castellani, 1912, trichomycosis axillarum. *C. thibiergei* Pinoy and Ravaut, 1909, nodular affection.	
VII. Due to fungi of the genera *Sporotrichum* Link, 1809, *Hemispora* Vuillemin, 1906, *Enantiothamnus* Pinoy, 1911, *Scopulariopsis* Bainier, 1907, *Cladosporium* Link, 1809, *Acremonium* Link, 1809, *Acladium* Link 1809	*Sporotrichum beurmanni* Matruchot and Ramond, 1905 *S. schencki* Hektoen and Perkins, 1900 *S. asteroides* Splendore, 1911 *S. indicum* Castellani, 1908	Varieties of sporotrichosis found in the tropics.
	Hemispora stellata Vuillemin, 1906 *Enantiothamnus braulti* Pinoy 1912 *Scopulariopsis blochi* Matruchot, 1911 *Cladosporium madagascariense* Verdun, 1913 *Acladium castellanii* Pinoy, 1916	Various types of gummatous affections.
VIII. Due to fungi of the genera *Aspergillus* Micheli, 1725, *Sterigmatocystis* Cramer, 1869, *Madurella* Brumpt, 1905, *Indiella* Brumpt, 1906, *Nocardia* Toni and Trevisan, 1889, *Cohnistreptothrix* Pinoy 1911, *Sporotrichum* Link, 1806, *Monosporium* Bonorden and Saccardo, 1898, *Glenospora* Berkeley and Curtis 1876	*Aspergillus bouffardi* Brumpt, 1906 *Sterigmatocystis nidulans* Eidam, 1883 *Madurella mycetomi* Laveran, 1902 *M. bovoi* Brumpt, 1910 *M. tozeuri* Nicolle and Pinoy, 1906 *Indiella mansoni* Brumpt, 1906 *I. reynieri* Brumpt, 1906 *I. somaliensis* Brumpt, 1906 *Nocardia maduræ* Vincent, 1894 *N. asteroides* Eppinger, 1890 *N. pelletieri* Laveran, 1906 *N. bovis* Harz, 1877 *C. israeli* Kruse, 1896 *Sporotrichum beurmanni* Matruchot and Ramond, 1905 *Monosporium apiospermum* Saccardo, 1911 *Glenospora khartoumensis* Chalmers and Archibald, 1916 *G. semoni* Chalmers and Archibald, 1917	Varieties of mycetoma.
IX. Due to fungi of the genera *Aspergillus* Micheli, 1727, *Penicillium* Link, 1809	*A. barbæ* Castellani, 1907, Aspergillosis of hairy parts. *P. barbæ* Castellani, 1907, Penicilliosis of hairy parts	

X. Due to fungi of the genera	*Aspergillus* Micheli, 1725 *Penicillium* Link, 1809 *Monilia* Persoon, 1791 *Montoyella* Castellani, 1907	Pinta.
XI. Due to fungi of the genus *Trichosporum* Behrend, 1890	*T. giganteum* Behrend, piedra.	
	Species as yet not well determined	Tropical varieties of nodular trichomycosis.
XII. Due to fungi of the genus *Pityrosporum* Sabouraud, 1903	*Pityrosporum cantliei* Castellani, 1907, variety of tropical seborrhœa.	

From the above table it will be seen that tropical dermatomycoses *sensû stricto*—viz., occurring only in the tropics—are comparatively few. Most of them are endemic also in temperate zones, though occurring there rarely, or at any rate less frequently than in the tropics. We may mention as examples tinea cruris and Madura foot. The same remark, however, applies to every other branch of tropical medicine.

The frequency of dermatomycoses in the tropics is probably due to the hot, damp climate being very favourable to the growth of vegetal parasites.

TINEA CRURIS (DHOBIE ITCH).

Synonyms.—Tinea tropicalis, Tinea inguinalis, Tinea axillaris, Eczema marginatum.

Definition.—The term 'tinea cruris' indicates a group of epidermophytoses and trichophytoses which are clinically characterized by their tendency to develop on the scroto-crural and inguinal regions.

Historical and Geographical.—Tinea cruris is extremely common all over the tropics: it is met with also in subtropical regions, and in temperate zones, being first described by Hebra in Europe under the name of eczema marginatum. In 1905, Castellani, as the result of the investigation of numerous cases, came to the conclusion that it should be separated from the ordinary forms of tinea corporis, and MacLeod suggested the name tinea cruris for the affection. For the fungus most frequently found in such cases, characterized by the yellowish cultures, Castellani used the name *Trichophyton cruris*. Pernet found and described a fungus for which Castellani suggested later the name *Trichophyton perneti*. In 1907 Sabouraud investigated in a complete manner the condition in France which he called tinea inguinalis. There can be no doubt that tinea inguinalis and dhobie itch, or tinea cruris, are the same entity, as Sabouraud and Pinoy, having compared cultures of *Epidermophyton cruris* isolated in Ceylon with those found in France, have found them identical.

Castellani's further researches have shown that other fungi besides *Ep. cruris* may give rise to tinea cruris, each species giving rise to a slightly different clinical variety of the eruption.

Ætiology.—According to Castellani's researches, at least three different species of *Epidermophytons* and one of *Trichophyton* may give rise to the eruption—*Epidermophyton cruris* Castellani, *Ep. perneti* Castellani, *Ep. rubrum* Castellani, and *Trichophyton nodoformans* Castellani—and there are probably several other not yet described species.

The description of these fungi is given in Chapter XXXVIII. (see p. 1014). Attempts at experimental reproduction of the disease made by Sabouraud and one of us in human beings and monkeys have failed.

Symptomatology.—The term 'dhobie itch' is used very loosely in the tropics by the lay public to denote practically any pruriginous skin affection. The term is, however, specially used to denote a form of severe pruriginous affection which mostly affects the inner surface of the thighs, occasionally the axillæ, and, in stout women, the regions under the breasts. It is in this stricter meaning that the term is used by medical men practising in the tropics.

The clinical features of the affection correspond to Hebra's 'eczema marginatum.' In a well-marked case the perineum, scrotum, and the inner surface of the thighs present large festooned patches, with an elevated abrupt margin; the whole of the patches are bright red, or, in a later period, the margin only is red, while the rest of the patch is of a fawnish colour, or even of normal colour. The pruritus is unbearable. Owing to scratching, a secondary pyogenic infection or an eczematous-like dermatitis may develop. The disease, if not properly treated, is extremely chronic; the condition improves during the cold season, but gets worse again during the hot months. Patients who suffer badly from dhobie itch may get almost well in a few days, without any treatment, on going to the hills; on returning to the plains the pruritus and all the other symptoms reappear. The affection has been known to last for many years. It is to be noted that after a time the eruption may spread to the other parts of the body—the abdomen, the trunk, legs, etc. In such situations it may develop in rings, or may form solid elevated dark red patches; while the disease may be clinically indistinguishable from ordinary tinea circinata. In some cases, though rarely, the eruption starts first on the chest and arms, and from there spreads later to the armpits and cruro-inguinal regions.

Clinical Varieties.—The above description mostly applies to the disease as produced by *Epidermophyton cruris*, which is the commonest fungus found, and by *Ep. perneti*. In the cases due to *Ep. rubrum* the affected parts often present from the very beginning an eczematoid appearance. The edge is perhaps not so raised as in other types of tinea cruris, but very abrupt, made up of numerous rather small, close-set papules, covered at times by minute bloody crusts due to scratching. The eruption may also be present in the shape of large complete or incomplete gyrations enclosing normal skin, or solid patches may be seen. The variety due to *Ep. rubrum* has great tendency to spread to other regions of the body.

In the cases caused by *Trichophyton nodoformans* the eruption has thick elevated margins, and along the edge deep-seated nodules resembling 'blind boils' are present, the fungus being capable of attacking the hair follicles and having pyogenic properties. The infection may spread from the inguinal regions to other parts of the body. We have seen a case presenting a nodular eruption due to this fungus in the groins, and at the same time presenting a typical kerion barbæ due to the same organism on the right cheek.

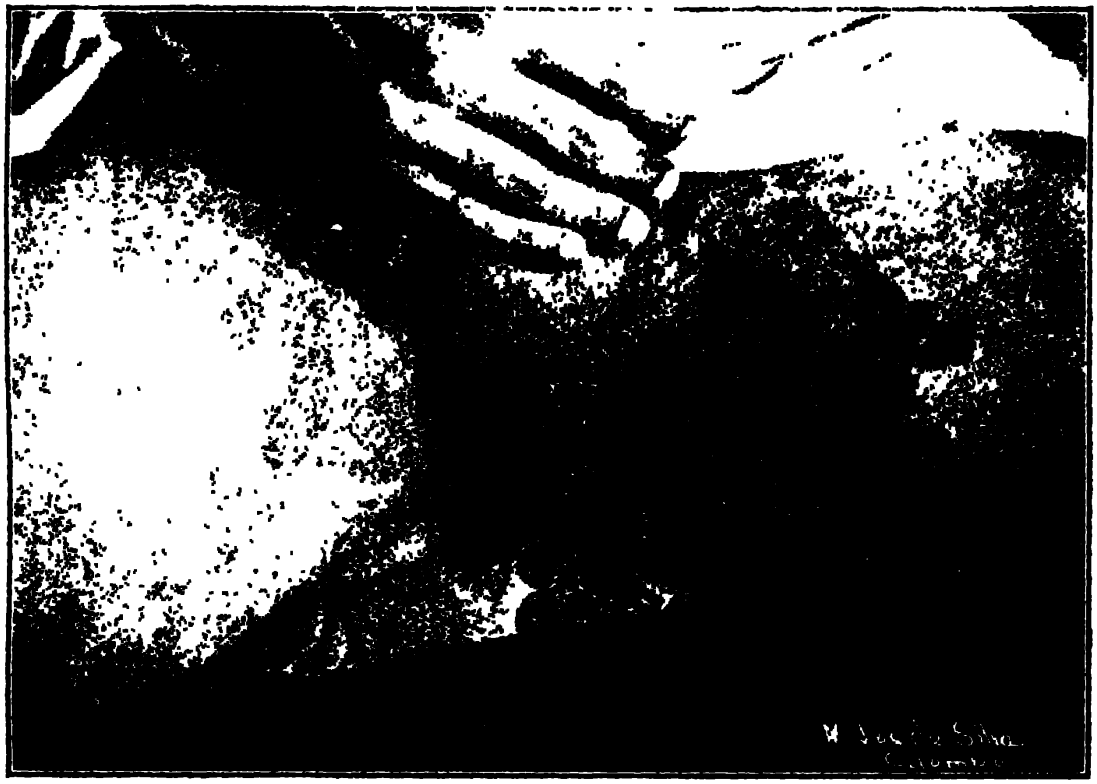

FIG. 801.—DHOBIE ITCH OF THE CRURO-INGUINAL REGIONS: TINEA CRURIS. From the same case (Tri [illegible] *yton cruri* Castellani) as [illegible] ed plate.

Regions of the Body affected.—The eruption, as already stated, is generally localized to the cruro-inguinal and axillary regions, hence the name 'tinea cruris seu inguinalis': but the same fungi may spread in many cases from those regions to any other part of the body, except the scalp. In some few cases the eruption may first appear on the arms or chest, etc., and then spread to the groins and armpits, or may never affect these regions. Hence the terms 'tinea cruris' and 'tinea inguinalis' are not altogether appropriate, and the term 'tinea tropicalis,' or the native term 'dhobie itch,' might be used as general terms to cover all the localizations.

A localization of great importance noted by Sabouraud, and later

PLATE VIII.

TINEA CRURIS

[illegible]

by Whitfield, is when the fungi invade the skin between the toes (tinea interdigitalis). In this situation the fungus—it is generally *Ep. cruris*—may remain for years, the fungus *per se* giving rise to practically no objective symptom, except perhaps a little scaliness, but generally induces very severe pruritus, especially in the hot weather. This localization of the fungus is often the starting-point of secondary bacterial affections causing a most distressing dermatitis, known to the planters by the name of 'mango toe,' and already described on p. 2036.

Communicability. Tinea cruris is known in the East as dhobie itch, from the popular belief that it is contracted from linen which has been contaminated while being washed by the dhobie (native laundryman). As to how far this belief is correct we are not in a position to say. We have never succeeded in finding the fungus in clothes newly received from the dhobie, either microscopically or by inoculating small portions of the linen in sugar media. We are, however, inclined to think that the popular belief may to a certain extent be correct. We have been told by old sufferers from dhobie itch, who used to be frequently reinfected, that on their ceasing to give their clothes to the dhobie, and having them washed in the house instead, the disease did not again affect them.* In Colombo dhobies are in the habit of washing the clothes in a lake,

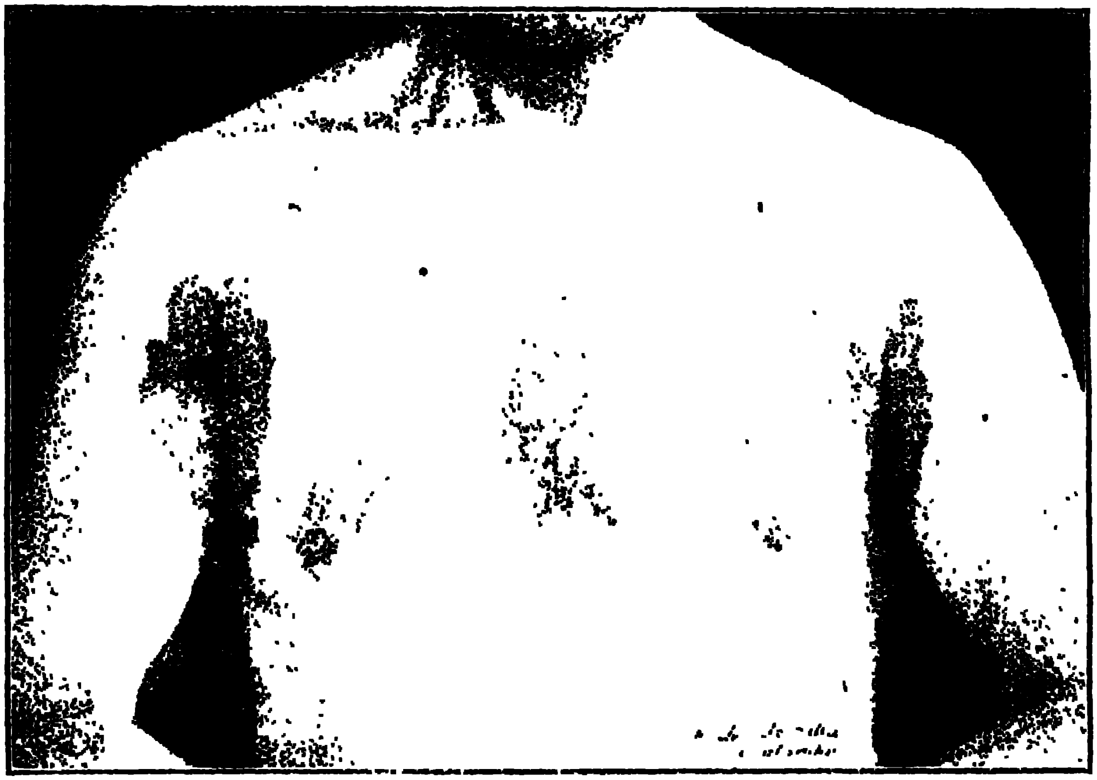

FIG. 802.—DHOBIE ITCH OF [illegible] AXILLARY REGIONS: TINEA AXILLARIS. Case due to *Epidermophyton cruris* Castellani.

or in small pools of water more or less stagnant. It is certain that clothes belonging to infected persons are washed together with other clothes. Dhobie itch is very contagious; true epidemics occur in schools and among soldiers in barracks.

Prognosis.—If the affection is not energetically treated, it has a tendency to become very chronic and last for years. Occasionally the eruption spreads to the whole body, forming rings or solid patches; at other times a distressing dermatitis develops on old dhobie-itch patches, due to scratching. Tinea cruris may disappear during the cold season, or when the patient goes to the hills, only to reappear as soon as the hot season commences. During the period of quiescence the skin of the affected regions often shows a brownish discoloration, furfuraceous, somewhat similar to erythrasma.

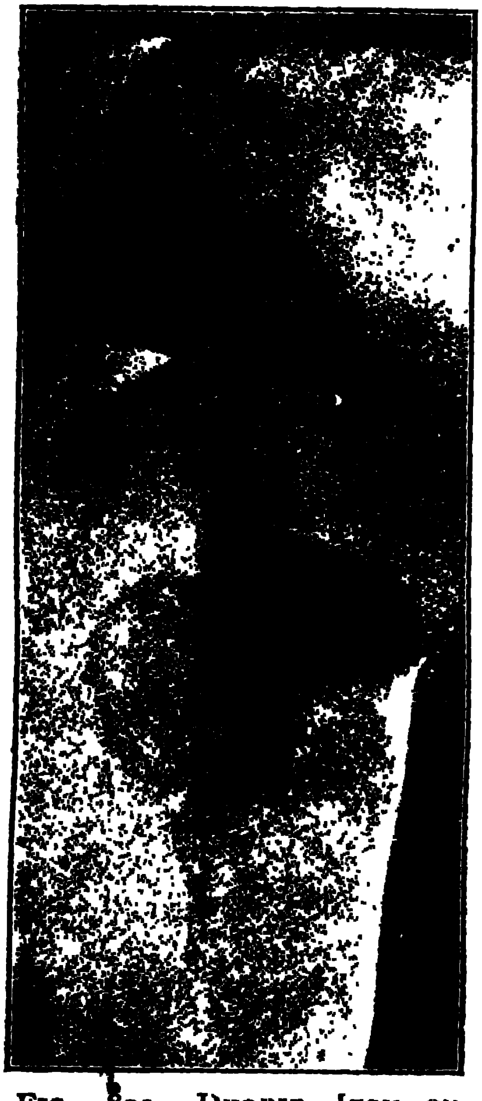

FIG 803.—DHOBIE ITCH OF THE AXILLARY REGIONS: TINEA AXILLARIS.

Case due to *Epidermophyton cruris* Castellani.

Diagnosis.—The diagnosis is easy in recent cases, the festooned appearance of the eruption, limited by a sharp, elevated, bright red edge, being quite typical. In old cases, especially when secondary lesions due to scratching are present, the diagnosis may be very difficult, the affection being often mistaken for eczema.

In doubtful cases the microscopical examination will be of great help. It must, however, be noted that in old cases the fungus may be extremely scarce, the mycelium being practically absent, and only a few spores being found; it is well to take the scrapings for microscopical examination from the edge of the eruption. The differential diagnosis must be made from erythrasma, intertrigo, and eczema.

In *erythrasma* the patches have a fawnish or dark reddish colour, and present often a fine pityriasic desquamation; the eruption is not limited by a raised red edge; the fungus *Nocardia minutissima* Burchardt is quite different from the fungi found in dhobie itch.

Intertrigo is very common in the tropics, especially in corpulent persons. The lesions are very superficial, have not a festooned contour, and the margin is not sensibly elevated; no *Epidermophyton*-

or *Trichophyton*-like fungi are found. Saccharomycetic intertrigo is rare; there is no elevated margin, and the fungus is found to be a Saccharomyces (*S. samboni*).

Primary eczema of the scrotum, and of the skin of the thighs in contact with it, is as frequent in the tropics as it is in temperate zones. The eczema is generally of the moist variety; the moist surface, the absence of the festooned elevated margin, distinguish it from tinea cruris. As already stated, however, an eczematous-like dermatitis due to scratching often develops after a time on old dhobie itch lesions.

Diagnosis of the Toes' Localization.—The complaining of severe itching between the toes, even if there are no objective symptoms whatever, should in the tropics always arouse the suspicion of a possible local fungus infection, especially if the patient suffers at the time, or has been suffering, from tinea cruris, and scrapings should be made and examined microscopically. It is important to make the diagnosis, as by treating the condition the development of that distressing dermatitis known as mango toe (see p. 2036) may often be prevented.

Treatment.—Our usual line of treatment is as follows:—

Mild Cases.—A resorcin salicylic ointment applied twice daily: Resorcin, ʒi.; salicylic acid, gr. x.; vaseline, lanoline, āā ʒiv. Tincture of iodine also is very efficacious, but induces a certain amount of smarting, and must be applied with care and in only very recent cases with no eczematoid lesions. In some cases we use Vleminckx' solution or lotio calcii sulphurati (slaked lime 4, sublimed sulphur 4, distilled water 35; boil together, evaporate, and filter to produce 20 of solution), pure or diluted. A sodium hyposulphite solution (sodium hyposulphite ʒii., aq. ℥i.) may also be used.

Severe Cases.—We use a chrysarobin ointment (2 to 5 per cent., a good formula being chrysarobin gr. x.-xxv., unguentum zinci ℥i.). The result is generally fairly successful. The patient should be informed that the medicine stains the linen, often irritates the skin, which may become œdematous and dusky red, and that occasionally unpleasant evidences of absorption may take place, with fever, diffuse erythema, and hæmaturia. Chrysarobin should never be used when there is some affection of the kidneys. The irritation induced by the chrysarobin ointment may be allayed by calamine lotion, lead lotion, or an ichthyol ointment 1 per cent.

Chrysarobin is obtained from araroba, which is known by the name of 'goa-powder' all over the East. The crude goa-powder, partly dissolved in vinegar, is often used, but frequently induces very severe inflammatory symptoms.

In obstinate cases we use local applications of turpentine-oil in the morning, and at night a resorcin salicylic ointment; if the parts are much inflamed, at night simply a boric ointment. This treatment gives good results. Turpentine is generally well borne, but patients often complain of a smarting and burning sensation a quarter of an hour after the application. Exceptionally one meets with patients who cannot stand turpentine.

Cases complicated with Eczematous Dermatitis and Fissures.—In such cases, in our experience, it is better to use at first a soothing treatment by lead lotion, or a solution of resorcin (½ to 1 per cent.), or glycerin. boracis in rose-water, with the object of first healing the eczematous lesions. Later, to the rhagades which so often develop in the inguinal regions, we apply a solution of nitrate of silver (arg. nitr., gr. v.-xv.; sp. æth. nitr., ʒi.). We touch with this solution the rhagades and the moist parts: this application is somewhat painful, but the pain soon disappears, and the fearful itching is relieved almost immediately: moreover, the nitrate of silver destroys the fungus. At night we apply a mild ichthyol ointment (1 per cent.) or hazeline cream all over the eruption: as soon as the parts have become less moist, we begin the chrysarobin treatment. A precaution, which must always be observed during and after the treatment, to prevent reinfection is to dust all the undergarments with antiseptic powder for instance, Manson's powder (ac. bor., zinc. ox., amyli, āā p. æq.): salicylic powder (ac. salicyl., gr. x.; talci venet., ʒi.); menthol powder (menthol, gr. v.: alcohol, q.s.; talci venet., ʒi.): dermatol powder (dermatol, gr. xx.: talci, ʒi.) It is advisable to wear small bathing-pants, which can be washed in the house.

Treatment of Generalized Dhobie Itch.- When the eruption is diffused all over the body, the simplest treatment is as a rule the application of tr. iodi or lin. iodi, treating only one portion at a time A chrysarobin ointment (2 to 5 per cent.) may also be used.

Treatment of Dhobie Itch localized to the Toes.- During the quiescent periods, or when there is only pruritus and a little scaliness, tincture of iodine may be used, or an alcoholic solution of salicylic acid (2 per cent.). When there are acute symptoms of dermatitis, the treatment must be at first a soothing one, as described on p. 2037.

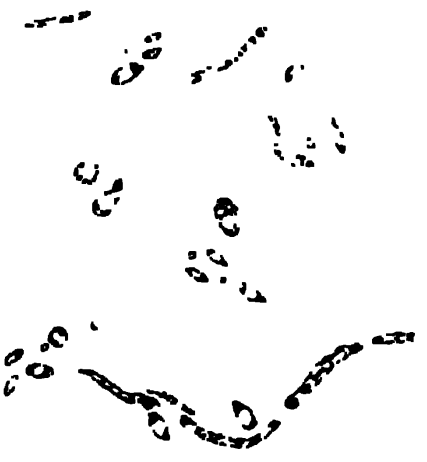

FIG. 804.—FUNGUS FOUND IN A VARIETY OF TINEA ALBA: *Atr. macfadyeni* CASTELLANI.

TINEA ALBA.

Remarks.—Tinea alba is in reality only a form of generalized dhobie itch; the term is applied to various diffuse trichophytic and epidermophytic conditions which give a white powdery appearance to the skin of the natives.

Historical.—This condition was first described by Castellani in 1905 in Ceylon. Cases have been recently reported by Pijper in South Africa.

Ætiology.—The commonest fungi found are *Epidermophyton rubrum* Castellani, 1909, and *Atrichophyton macfadyeni* Castellani, 1905 (*Trichophyton macfadyeni*), the description of which is given on pp. 1009 and 1016.

Symptomatology.—The arms, legs, chest, and occasionally the whole body, present a diffuse eruption of white powdery appearance, this being due to the very numerous small white pityriasic squamæ present. The margins of the eruption, when the causative fungus is *Ep. rubrum,* may be distinctly raised and dotted with minute, close-set papules.

Course and Prognosis.—The course is very chronic. Apparently the fungi have a disturbing action on the production of pigment in the skin, and after some years white leucodermic patches may develop, in which no fungus is found.

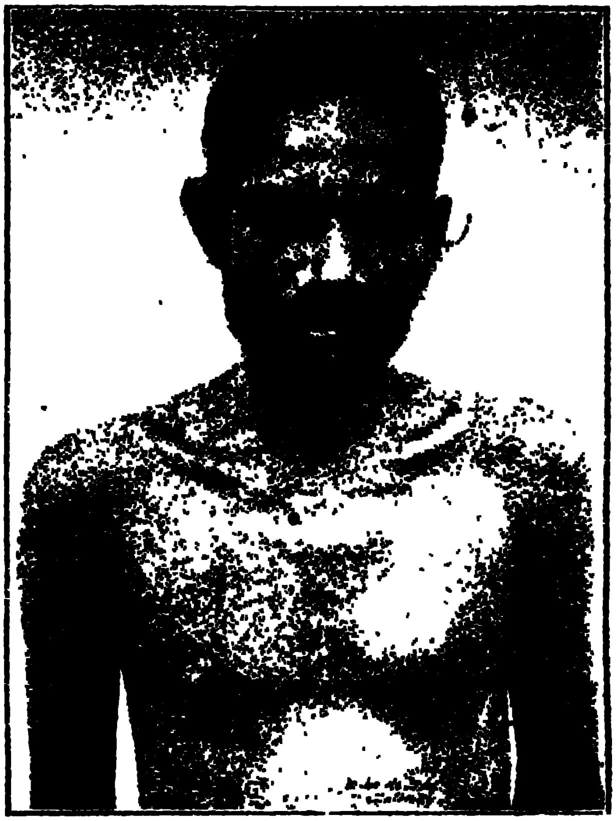

FIG ALBA DUE TO *ioum* CASTELLI

Diagnosis.—This is based on the diffuse eruption with the abundant fine pityriasic desquamation, and with well-marked limits—and the microscopical examination. It is quite easily distinguished from tinea imbricata by the squamæ being pityriasic, very small, easily detached. In leucoderma the surface is smooth, no squamæ being present and no fungus found. As already stated, however, if the eruption is left untreated for a long time, leucodermic patches may develop.

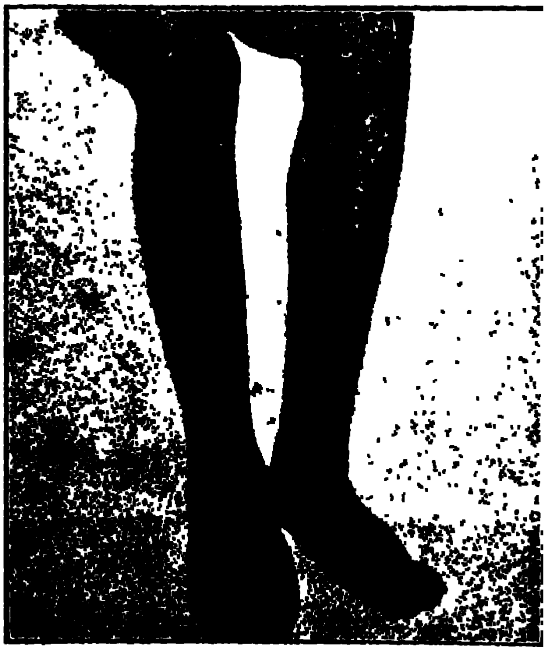

FIG. 806.—TINEA ALBA.

Treatment.—The best treatment is by a chrysarobin ointment (2 to 5 per cent.), applied with the precautions already mentioned. Tincture of iodine and liniment of iodine may also be used.

TINEA ALBIGENA.

This trichophytosis was first described by Nieuwenhuis in Java. Nieuwenhuis' researches have been confirmed and enlarged by Jeanselme in Indo-China and in Siam; in the latter country the disease is known as *khi*. The disease is fairly common in the Malay Archipelago, and is occasionally met with in Ceylon.

Ætiology.—The affection is due to a *Trichophyton* first described by Nieuwenhuis—*T. albiscicans* Nieuwenhuis, 1907.

The spores in fresh preparations from scrapings are almost always absent; the mycelium tubes are straight, occasionally showing a double contour; they are often dichotomous. Nieuwenhuis has grown the fungus, using Sabouraud's sugar media; the growth is very slow; the colonies are whitish, and show a powdery surface.

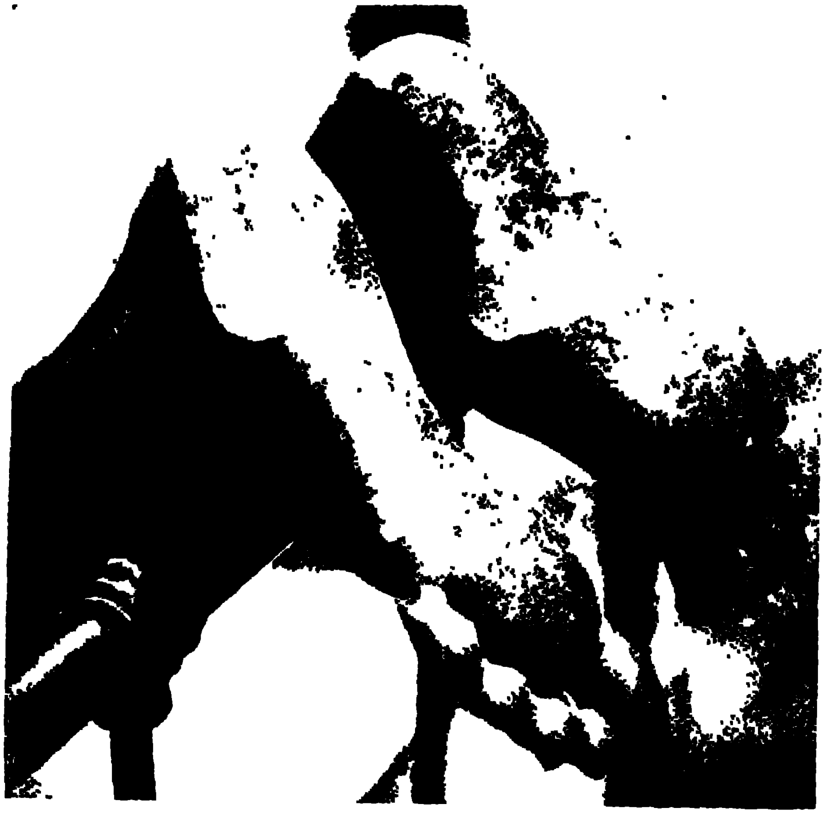

FIG. 807.—TINEA ALBIGENA.

Symptomatology.—The eruption generally affects the palms of the hands and the soles of the feet, but may extend to the forearms and legs, and may affect the nails. It begins with the appearance of small pruriginous spots on the palms and soles; the epidermis becomes raised, and bullæ develop, containing at first clear serum; the bullæ break, and the skin remains dry and peels off; the parts remain tender, and there is desquamation and pruritus. A process of diffuse keratosis develops, the palms and soles becoming double their usual thickness; deep fissures may be formed at the natural folds. Several horny semidetached discs can often be seen at the dilated orifices of the sweat glands. The affection is very chronic; it may begin in youth or in adult life. After some time a process of apigmentation of the skin sets in, white patches, leucoderma-like, developing, and extending often to the legs and arms.

Treatment.—Tincture of iodine and chrysarobin ointment (1 to 5 per cent.) answer fairly well, but the apigmented patches are not cured.

TINEA SABOURAUDI TROPICALIS.

This trichophytosis was first described by Sabouraud in patients returning from Indo-China, Japan, and Tonkin. We have seen a few cases in Ceylon.

Ætiology. The disease is caused by the fungus *Trichophyton blanchardi* Castellani, 1905 (synonym, *T. sabouraudi* Castellani, 1905). The term *T. sabouraudi* cannot be applied to this *Trichophyton*, as this name has already been used for another *Trichophyton* -*T. sabouraudi* R. Blanchard, 1905. This fungus cannot be grown on Sabouraud's media or any other media we have tried. Microscopically the mycelial tubes do not show a double contour, and are not very straight; they are often banana-shaped. The segments of the mycelium are all separated: the mycelial spores are roundish, and are shed without forming a filament by their union. They are of various sizes.

Symptomatology.- The eruption generally commences on the uncovered parts of the body, generally on the legs: the patients often state that they think the disease is due to prolonged immersion in stagnant water. The affection begins with erythematous patches, the surfaces of which are covered with minute pityriasic squamæ. After reaching the diameter of about 1 or 1½ inches, the patches become circinate. The circination, however, is incomplete; it is only segmentary. In dependent positions large polycylic patches may be seen, but only one-half or one-third of the circles are clearly seen, the rest being badly defined. The base of the patches at this stage is of a very dark bistre-brown colour. The border shows polymorphic lesions, fine pityriasic squamæ, minute vesicles and papules. The pruritus is very marked, and excoriations, due to scratching, are constantly present. In chronic cases a thickening of the skin, with lichenification, takes place, specially at the circinate borders.

Treatment.- - The disease is difficult of cure in the tropics, though it may disappear spontaneously on the patient proceeding to Europe. Chrysarobin ointment (1 to 4 per cent.) is the best treatment.

TINEA NIGRO-CIRCINATA.

This trichophytosis has been observed by one of us among Sinhalese natives.

Ætiology.—The eruption is due to a *Trichophyton*—*T. ceylonense* Castellani, 1908. The spores are very few in number, roundish, rather large (4 μ), and showing a double contour. The mycelial tubes are about 3½ μ in breadth, generally straight. The fungus does not grow on any of the ordinary or Sabouraud's media.

Symptomatology.—The eruption is found most frequently on the neck and scrotum, and consists of a few rings with thick, elevated margins, the encircled skin being black—much darker than the healthy skin—but not thickened nor presenting papules, vesicles, or pustules. The edge is thick, elevated, of a dark colour, with the upper portion pinkish or occasionally covered by a dark crust. The eruption often heals spontaneously, leaving dark roundish patches at the previous seat of the lesions.

Prognosis.—The eruption may disappear spontaneously, and the treatment is easy.

Diagnosis.—The only dermatomycosis to which it has a slight resemblance is *Tinea sabouraudi*. The latter, however, is very chronic, and invades large portions of the body; the rings are segmentary, not complete, and the edge is not so thick and elevated.

The condition may have also to be distinguished from a circinate frambœside or ringworm yaws, in which no fungus is found, while *Treponema pertenue* Castellani, is present.

Treatment.—Tincture of iodine, freely applied, answers well.

TINEA CAPITIS TROPICALIS.

Definition.—Tinea capitis tropicalis is ringworm of the head as seen in the tropics.

History.—Celsus in the second chapter of the sixth book of his 'De Medicina' gives an account of ringworm of the head under the name 'porrigo.' His words are: 'Porrigo autem est, ubi inter pilos quædam quasi squamulæ surgunt, eæque a cute resolvuntur; et interdum madent, multo sæpius siccæ sunt.'

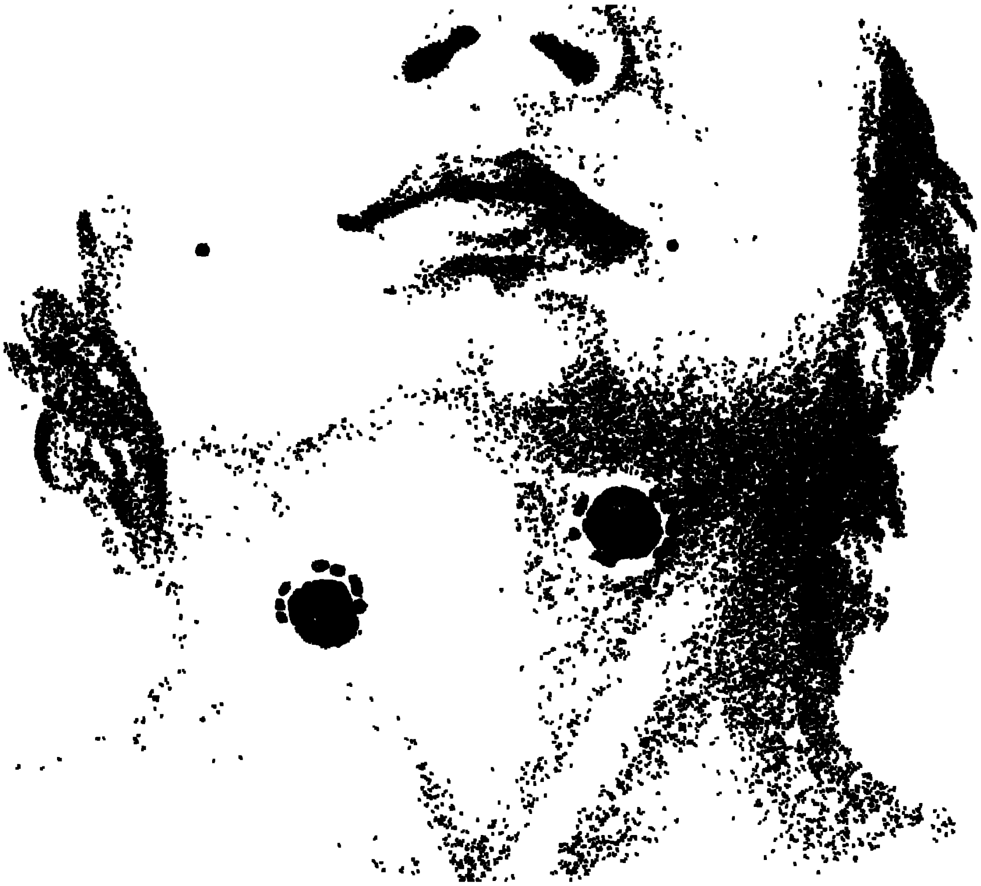
Bishop Fortunatus, who lived in the sixth century A.D., uses the name 'tinea' in the following passage: 'Lavans capita egenorum, defricans quicquid erat, crustam, scabiem, tineam nec purulentam fastidiens.'

In the tenth century Ali ben Abbas (often written Haly), who lived in Persia, described the complaint under the terms 'sahafati' and 'alvathim.'

The Anglo-Saxons applied the word 'teter' to any kind of skin disease which itched, and in this form it was used in middle English. In the fourteenth century Guy de Chauliac wrote a work on surgery in which he used the word 'teigne,' deriving it from 'tenir.'

With the advent of printing it was called 'tetters,' in England

PLATE IX.



TINEA NIGRO CIRCINATA.

Geo. Waterston & Sons, Ltd. Edin.

To face page [illegible]

(*vide* Langham's 'Garden of Health,' 1633), but in or before the sixteenth century the word 'ringworm' (*vide* Levins or Levens, 'Manipulus Vocabulorum,' London, 1570) had appeared for the disease tinea circinata. In 1695 Willis in his 'London Practice of Physick' devoted a chapter to the subject of the running scab, tetter, or ringworm.

With a history such as this it is not astonishing that the early English writers on tropical medicine refer to the same disease as seen in tropical countries.

Thus in 1746, in his work on the diseases of Barbados, Hillary says that it was noticed by the first voyagers to the West Indies, and that it probably is the same disease as that called by the natives 'cowrap.' He gives a good clinical description of tinea circinata as he saw it in Barbados, and he is supported by Wright ('Essays on the Malignant Fever of the West Indies'), who stated that it was common in Jamaica.

Winterbottom in 1803, under the term 'herpes,' describes the disease in Sierra Leone, calling it serpigo, ringworm, or tetters, and distinguishing it from kra-kra.

So far it would appear as though only the body ringworm or tinea circinata was meant by the terms 'tetters' and 'ringworm,' but in 1817 Bateman, the pupil of Willan, who completed his master's great work on skin diseases, published an atlas on the same subject, in which Plate XXXIX. induces Sabouraud to believe that he recognized the identity of the two conditions. In 1824 Plumbe showed that inoculation of ringworm of the scalp would cause ringworm of the body, and *vice versa*.

These publications appear to have stirred the practitioners of the tropics to study the disease, as it was described in India by Young, in 1826, and in the Malay Archipelago by Lesson, in 1829.

In 1832 Alibert published the first edition of his celebrated 'Monographie des Dermatoses,' which stimulated the continental medical mind of the day, as is reflected by Smith's description of the disease in Peru, in 1840, and Pruner's in Egypt, in 1847.

In 1839 Schönlein discovered the fungus causing favus.

In 1842 Gruby, who had already repeated Schoenlein's observations on the parasite of favus, discovered a new cryptogam in tinea barbæ, which was an ecto-endothrix.

In 1843 he found *Microsporum audouini*, and six months later, on April 1, 1844, he described an endothrix as the parasite of herpes tonsurans. It is, however, but just to state that, without Sabouraud's generous treatment, much of Gruby's work might have been permanently overlooked.

In 1845 Malmsten gave the name of *Trichophyton* to the parasite of tinea tonsurans.

It is asked that the reader will kindly observe the spelling of the names of these two genera. Gruby called the one *Microsporum*, not Microsporon, and Malmstén named the other *Trichophyton*, not Trichophytum.

These researches naturally aroused much interest, and in 1855 Heymann showed that the disease existed in the East Indies, but it is noticeable that he makes no mention of observing a parasite in the affection.

In 1874 Blanc described the occurrence of the disease in Abyssinia, where Merab states that it is very common, and where it is treated by the juice from the fruits and leaves of *Bryonia deoica* and by tobacco powder, as well as by sulphur ointment.

In 1872 the Army Sanitation Commission induced the British Government to instruct Tilbury Fox and Farquhar to obtain a better knowledge of the endemic skin diseases of India, and to bring about an agreement between the profession in India and England as to nomenclature, typical characters, varieties, and probable causes of these diseases. Thanks to the interest of Lord Granville, Lord Kimberley, and Sir Alexander Armstrong, this inquiry was extended to China, Japan, Egypt, Algeria, the West Indies, and Honolulu, and the finished report was published in 1876.

The net result of this inquiry as far as ringworm was concerned was unfortunate, as it led to the dogmatic assertion that the ringworm of the body in the tropics was the same as that of temperate climes.

In 1873 van Leent drew attention to the large number of cases of ringworm of the head in Chinese in the island of Banka, in Malaysia.

In 1878 Corre gave a description of the disease and its parasite as seen in Nossi-Bé.

From 1890 the possibility of plurality in the species of Trichophyton was raised, but it was not until Sabouraud in 1892 began those brilliant researches which he has carried on to the present day that this was definitely established. In this year he showed that ringworm of the scalp could be divided into two main groups—viz., those with small spores belonging to the genus *Microsporum* Gruby, 1843, and those with large spores belonging to the genus *Trichophyton* Malmsten, 1848. The large-spored fungi of the scalp he divided into five species, which were afterwards named *Trichophyton crateriforme* = *T. tonsurans*, *T. acuminatum* = *T. sabouraudi*, *T. gypseum*, *T. violaceum*, and *T. rosaceum*.

In 1893 he further divided the Trichophytons into two groups, which he named Endothrix and Ecto-Endothrix (Ectothrix), and which corresponded with Gruby's two divisions. His researches were speedily confirmed by many observers, among whom may be mentioned Adamson, Colcott Fox, Malcolm Morris, White, and Mibelli.

In 1900 Matruchot and Dassonville showed that the Trichophytons were closely allied to the Gymnoascaceæ, and that *Ctenomyces serrata* Eidam, 1880, when injected into animals produced a Trichophyton-like mycelium and eruption.

The further history may perhaps be better discussed according to the countries.

Brazil.—The history of ringworm in Brazil appears to date from the appearance of Silva Araujo's 'Atlas des Maladies de la Peau,' which contained an account of favus and of a Trichophyton causing sycosis, both supported by microscopical observations.

Later Fernando Terra grew *Achorion schoenleini* from an atypical case of favus, and some form of fungus from a case of tinea capitis tropicalis, which was traceable to infection from a cat, and was therefore probably *T. felineum*. The sixth Brazilian Congress of Medicine and Surgery, held in 1907, is remarkable for the appearance of papers on ringworm in which the parasitic fungi were studied according to Sabouraud's classical methods. It was at this meeting that Rabello announced that he had found *T. violaceum*, *M. audouini*, and *M. lanosum*.

In 1909 Lindenberg reported the presence of *T. sabouraudi*. Horta announced that *M. felineum* has been found in a considerable number of cases at São Paulo, and also isolated *T. album* Sabouraud, 1907.

In 1911 Horta discovered *M. flavescens*, and in 1914 he found a new Trichophyton, which was subsequently described and named *T. griseum* by Vasconcellos.

Argentina. In 1907 Uriburu discovered *M fulvum*, and in 1909 *T. exsiccatum* and *T. polygonum*.

Central America.—In 1913 Brumpt named a peculiar parasite, discovered by Darier in a dermatosis resembling pinta, *T. carateum*. This disease was found in Central America.

Africa.—In 1896 Cournont described two forms of tinea capitis tropicalis seen in Senegal

In 1902 Bodin found *T. violaceum* Bodin in North Africa.

In 1904 Jeanselme announced that Coumnont had found *M. audouini* among the negroes of Senegal, and that Sabouraud and himself had found a Trichophyton (subsequently named *T. circonvolutum* by Sabouraud in 1909) in white people returning from the Western Sudan.

In 1912 Joyeux discovered *T. soudanense* in the Western Sudan.

Ceylon.—In 1905 Castellani discovered *T. violaceum* var. *decalvans* in tinea capitis tropicalis, *T. macfadyeni* Castellani, in tinea corporis tropicalis, and *T. blanchardi* Castellani in tinea sabouraudi tropicalis a term also used for the disease caused by *T. circonvolutum* Sabouraud.

In 1908 he observed *T. ceylonense* Castellani, in cases of tinea nigro-circinata.

In 1912 he found *T. nodoformans* Castellani in tinea barbæ tropicalis and in tinea ciliorum.

Tropical Queensland.—In 1914 Priestley discovered *M. scorteum* Priestley in tinea corporis tropicalis.

In the Anglo-Egyptian Sudan Chalmers and Marshall found *Trichophyton currii* Chalmers and Marshall, 1914, to be the cause of an epidemic, and later *Trichophyton discoides* Sabouraud, 1909, in one case, while Chalmers and Macdonald have met with numbers of cases due to *T. violaceum* Bodin, 1902, var. *khartoumense*.

Geographical Distribution.—Tinea capitis is found in every part of the tropics, but its incidence varies from country to country, and is far less common than epidermophytoses and trichophytoses of the body.

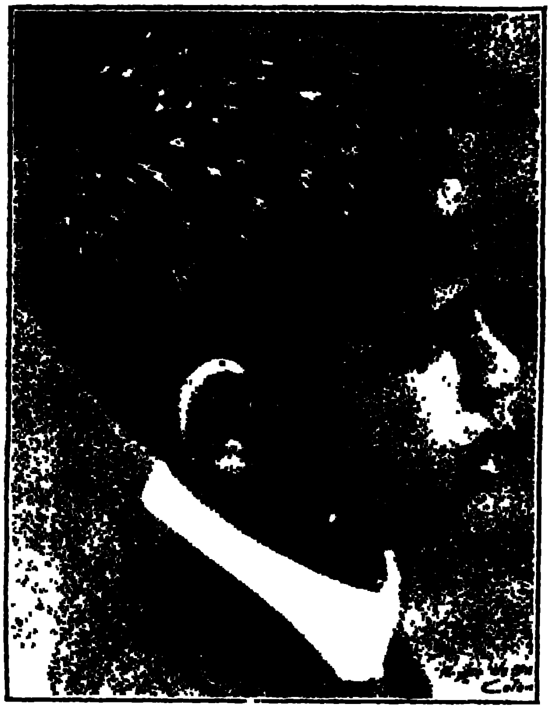


Fig. 808. Tinea Capitis due
Tr. violaceum Bodin var. *decalvan*

In our experience tinea capitis is less common in India, Ceylon, and tropical Africa than in Europe and America. On the other hand, it is extremely common in American negroes.

Ætiology. — The following fungi have been found in cases of tinea capitis tropicalis:—

Genus Microsporum Gruby, 1843.

1. *M. audouini* Gruby, 1843, in Brazil, Western Sudan, Northern Africa and Madagascar.
2. *M. fulvum* Uriburú, 1907, in the Argentine.
3. *M. scorteum* Priestley, 1914, in Tropical Queensland.

Genus Trichophyton Malmsten, 1848.

1. *T. circonvolutum* Sabouraud, 1909, in Senegal and Dahomey.
2. *T. exsiccatum* Uriburú, 1909, in the Argentine.
3. *T. polygonum* Uriburú, 1909, in the Argentine.
4. *T. sabouraudi* R. Blanchard, 1895, in Brazil.
5. *T. soudanense* Joyeux, 1912, in Western Sudan.
6. *T. violaceum* Bodin, 1902, in North Africa.
7. *T. violaceum* Bodin, 1902, var. *decalvans* Castellani, 1905, in Ceylon.
8. *T. violaceum* Bodin, 1902, var. *khartoumense* Chalmers and Macdonald, 1915, in the Sudan.
9. *T. currii* Chalmers and Marshall, 1914, in the Sudan.

Genus Ectotrichophyton Castellani and Chalmers, 1918.

E. discoides (Sabouraud, 1909) in the Anglo-Egyptian Sudan.

Genus Achorion Remak, 1845.

1. *A. schoenleini* Lebert, 1845, in the Anglo-Egyptian Sudan Egypt, Tunis, Tripoli, Algeria, China, causing favus.
2. *A. quinckeanum* Zopf, 1890; the cause of mouse-favus, rarely infects man.

3. *A. gypseum* Bodin, 1907; very rare.

The description of all these fungi is found in Chapter XXXVIII., p. 988.

Symptomatology.—It may be said in a general way that the principal clinical signs are the same in the tropical types of the affection as in the temperate zones, though the medical man who has studied the subject thoroughly will soon be able to detect small clinical differences, and will soon realize that as a general rule each species of fungus gives rise to a slightly different type of disease.

Tinea Capitis Microsporica (*Microsporosis*).—Tinea capitis due to fungi of the genus microsporum, usually known by the term microsporons in dermatological literature, is rare in tropical and subtropical countries. The affection attacks, usually, only children. The affected patches are studded with stumps of broken hair, which are loosened and brittle, have lost their natural gloss, and show a whitened appearance caused by the fungus producing a greyish sheath round the hair. The microscopical examination of the affected hair after treatment with liquor potassæ will show presence of so-called spores, roundish or ovoid, 2-4 μ in diameter, irregularly distributed, while those of the trichophytons are often larger (3-8 μ), square with rounded angles, or somewhat oblong, and arranged in definite regular chains.

Tinea Capitis Trichophytica (*Trichophytosis*).—This is common in the tropics and may be caused by a number of trichophytons which have been mentioned in the Ætiology. In Chapter XXVIII., p. 995, we have given a botanical classification of the genus Trichophyton, creating several subgenera. In most dermatological works, however, a simpler classification is followed. Two groups are differentiated: *endothrix* and *endo-ectothrix*, the latter corresponding to the original Sabouraud's ectothrix. The endo-ectothrix group is subdivided into two types: with large spores (megaspores), with small spores (microïdes). Those of the microïdes type produce a greyish sheath round the hairs, like the microsporons, but the so-called spores are arranged in regular chains, a feature never observed in the microsporons. The microïdes trichophytons are pyogenic, and often cause kerion.

As we have already stated, each species of trichophyton gives rise to a slightly different clinical type of the affection. Among the many types we may briefly notice "Black dot tinea tonsurans" and "Tinea decalvans tropicalis."

Black-dot Tinea Tonsurans.—This type is common in Europe, but is at times observed also in subtropical and tropical countries. It is caused by *Trichophyton sabouraudi* Blanchard, usually known in dermatological literature by the name of *Trichophyton acuminatum*. The scalp presents scurvy patches with minute dark dots, best seen with a lens. These dots are pigmented, coiled up stumps.

Tinea Decalvans Tropicalis.—This variety, described by Castellani, is common in Ceylon. It generally attacks children, especially of the moormen community. The scalp presents one or several white patches covered with an enormous number of heaped-up white pityriasic scales. The scales and the broken hairs, examined microscopically, show presence of an endo-ectothrix fungus, which, when cultivated, shows some characters of *T. violaceum* Bodin (*T. violaceum* Bodin var. *decalvans* Castellani). A very serious symptom is that the patches as a rule remain permanently bald.

Tinea Capitis Favica (*Favus*).—This affection, common in Southern and Eastern Europe, is found in some subtropical countries, such as certain parts of North Africa and China, but is rare in the tropics. The condition is recognized by the sulphur-coloured cup-shaped scabs, the peculiar mousy odour and presence of atrophic scarring. The hair is lustreless and discoloured, but does not break off as in ringworm.

Diagnosis.—This is based on the clinical characters mentioned, and on the microscopical examination of the hairs and squamæ in liquor potassæ. Cultural methods should also be used.

Prognosis. This is rather bad in the common variety found in Ceylon, due to *T. violaceum* var. *decalvans*, as the patches in most cases remain permanently bald, though fortunately they are, as a rule, of small dimensions. The treatment of every type of tinea capitis is long unless X rays are used.

Treatment. The Röntgen rays treatment, using Sabouraud's method, is by far the best and quickest. Details on the technique will be found in any up-to-date book on dermatology. In many tropical places this treatment is out of the question, and epilation and application of turpentine oil, tincture of iodine, or - with care - a chrysarobin ointment (2 to 5 per cent.) must be resorted to.

Garrett recommends the application of liquor ferri perchloridi fort. (B.P.) after thorough cleaning of the patches with benzene Sabouraud at one time recommended the internal administration of tallium acetate. Cicero uses a 5 per cent solution giving as many drops as is represented by twice the number of kilogrammes of the child's weight.

TINEA BARBÆ TROPICALIS.

The same remarks can be made on this subject as on tinea capitis. Cases are found in the tropics, though apparently less frequently than in temperate zones, and the fungi have so far been very little investigated. In Northern Africa a fungus commonly found is *Trichophyton violaceum* Bodin: in Ceylon *T. nodoformans* Castellani is often found.

Symptomatology.—The dry variety, with scaly, often gyrated lesions, and the pustular variety, with purulent folliculitis, can be distinguished.

We have seen a typical case of kerion barbæ due to *T. nodoformans* in a person who was suffering from tinea cruris due to the same fungus.

Diagnosis.—The diagnosis, in the pustular type, is based on the spreading folliculitis with brawny swelling and the microscopical examination of the hair: in the scaly type, on the frequent gyrate type of the eruption and the microscopical examination of the scales and hair.

Prognosis.—The disease takes a long time to get well, even under appropriate treatment.

Treatment.—This consists in epilation of the affected region, each day clearing a square inch or so, followed by the application of some antiseptic ointment such as Crocker's ointment of sulphur, ʒss.-ʒi.: ac. carbol., ʒss.; lanolin c̄ oleo, ℥i.: or oleate of copper, ʒss. to ℥i.

Tinea Ciliorum.

We have seen a case of this affection in a man suffering from generalized dhobie itch, due to *T. nodoformans*. The lid was swollen and red, many cilia were broken, and there was purulent inflammation of the hair follicles.

TINEA UNGUIUM TROPICALIS.

Synonym.- Onychomycosis tropicalis.

Cases of tinea unguium, or onychomycosis, occur in the tropics, and are generally due to the same fungi producing dhobie itch, both *Epidermophytons* and *Trichophytons*. The nails of the fingers as well as of the toes may be affected. Tinea unguium may be caused also by fungi of the genus *Endodermophyton*, the nails being often affected in tinea imbricata.

Symptomatology. The affected nails have often a peculiar yellowish opaque or blackish discoloration, and a rough surface; they become brittle, and splitting and chipping of the free border takes place.

The diagnosis is principally based on the microscopical examination of scrapings. A soaking in liq. potassæ (40 per cent.) for twenty-four hours is often necessary to disintegrate the nail substance and to find the fungi.

Treatment. This is most difficult. The affected nails must be softened by rubbing in liquor potassæ, and then wet dressings of hyposulphite of soda (25 per cent.), or a solution of potassium iodide grms. x., iodine grm. i., water 1,000 c.c., must be regularly applied. In the onychomycosis found in cases suffering, or having suffered, from tinea imbricata the daily application of resorcin in tincture of benzoin (ʒi. to ℥i.) is useful.

TINEA IMBRICATA (TOKELAU).

Definition.—The term 'tinea imbricata' is used to denote a tropical dermatomycosis, or, more correctly, a group of dermatomycoses, due to fungi of the genus *Endodermophyton* Castellani, and clinically characterized by the presence of extensive, flaky, scaly patches, the scales being large, tissue-paper-like, firmly adherent by their bases, and arranged in concentric rings or parallel lines.

Synonyms. As is the case with several other tropical diseases, such as framboesia and Oriental sore, there is a very large number of synonyms, which may be classified as follows:-

(*a*) From the name of the centres where the disease is rife: for instance, the term 'Tokelau,' generally used by French writers, is in reality the name of an island, Tokelau, where the malady is very common. Other synonyms are 'Tokelau ringworm,' used by Tilbury Fox, 'Bowditch ringworm,' the name Bowditch being used by some writers to indicate the island of Tokelau, 'South-west Gune,' the term 'gune' meaning skin.

(*b*) From the name of the patient who first introduced the disease in certain countries. In the island of Tokelau, for instance, the disease used to be known as 'Le Pita,' from 'Peter,' the name of the native of Tamana, one of the Gilbert Islands, who, according to Turner, in 1850 introduced the disease into Tokelau.

(*c*) From certain clinical appearances: 'Tropical ichthyosis,' a bad term, as in the tropics true ichthyosis is far from rare; 'Dermatomycosis chronica figurata exfoliativa' (Tamson); 'Herpes farinosus' (Ritter); 'Herpes desquamans' (Turner); 'Tinea imbricata,' a term introduced by Manson, and which is now the one most generally used.

(*d*) From the generic name given to the fungus: 'Aspergillosis' of Wehmer; 'Lepidophytosis' of Tribondeau; 'Endodermophytosis' of Castellani.

(*e*) From the name of the authors who have more completely studied the disease: 'Manson's herpes,' 'Turner's herpes,' etc., the term 'herpes' being used by Roux and others in the obsolete meaning of epiphytic skin disease.

(*f*) Terms apparently of unknown origin, such as 'Gugo,' a denomination much used in the Marshall Islands; 'Cascado,' a term used in the Molucca Islands; 'Buckwar,' etc.

History.—The first recognizable account of the condition is to be found in Dampier's 'Voyage Round the World,' published in 1789. Dampier saw the disease in the Philippine Islands in Mindanoa, in Guam, and in the Ladrone Islands. About the end of the same century Dentrescasteaux described cases of the same condition in Tonga. In 1811 Marsden observed it among the natives of Polo Mas, on the west coast of Sumatra. In Alibert's 'Atlas,' published in 1832, there is a reference to the disease. In 1841 the disease was recognized by the medical officers attached to the United States Exploratory Expedition led by Commodore Wilkes, and Fox in 1844 described it under the name of 'gune,' the term used by the Gilbert Island natives.

In the reports of the Samoa Medical Mission for the year 1869 there is a good description of the malady by Geo. Turner. In 1874 Tilbury Fox gave a description of the complaint under the term 'Tokelau ringworm,' and noted the presence of a fungus in the scales sent to him from the tropics. He considered it to be identical, or very similar to, the fungus of European ringworm. From the drawings given the fungus described by him seems, however, not to have been a trichophyton-like organism, but an aspergillus-like contamination. From that time discussion began, which went on for several years, on the subject whether the disease was a separate entity or merely European 'ringworm' modified by the different climatic conditions. Apparently the great majority of the European authorities, who, however, had no personal experience of the condition, were against considering the disease a separate one, while the medical men practising in the tropics generally believed it to be a different disease from ringworm. Valuable researches were carried out by McGregor in 1870 and Königer in 1878. Manson's researches on the malady—in China from 1879 to 1882—are by far the most important. He gave a complete clinical description of the malady, and introduced the very appropriate name of tinea imbricata; moreover, he very correctly described the microscopical appearances of its fungus, though, as might be expected, using the technique of that time, attempts at growing it did not succeed. More recently the condition has been studied by Tribondeau, Nieuwenhuis, Wehmer, and many others. Castellani has succeeded in growing the fungus artificially, and in reproducing the disease by inoculating pure cultures of it; he has shown also that there is more than one variety of the affection and more than one species of the fungus. He has

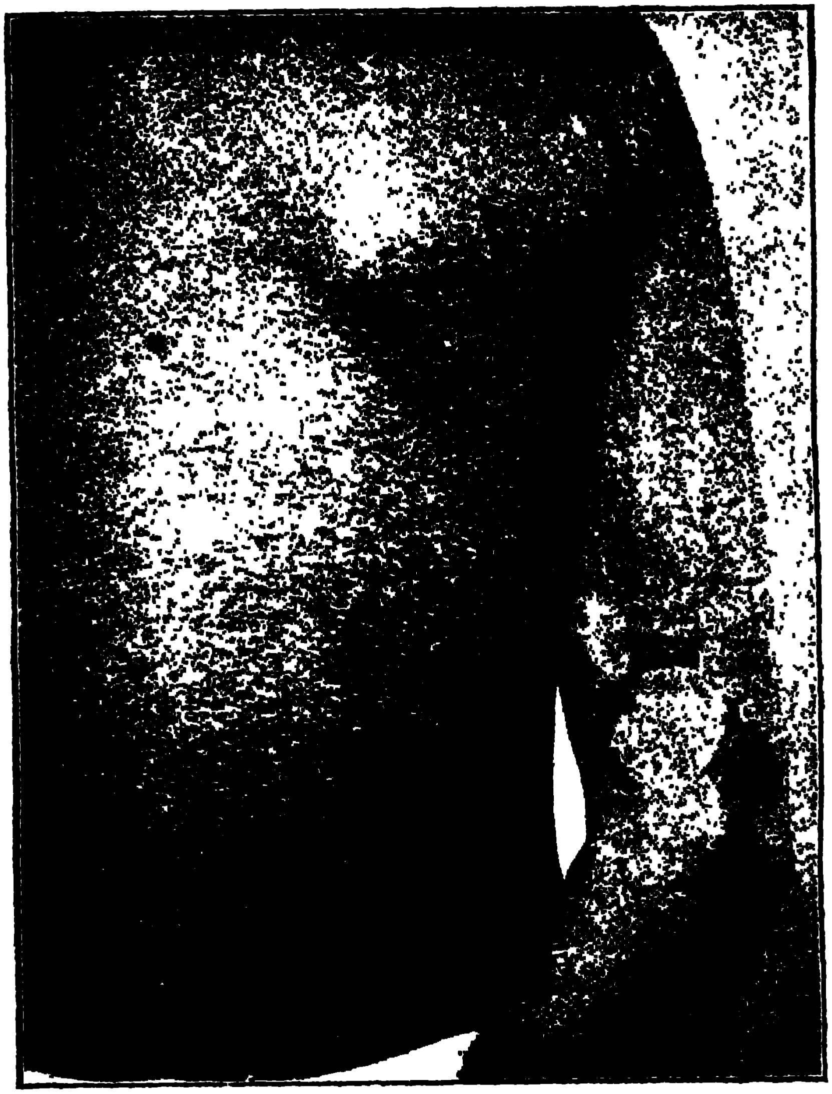

Fig. 809.—Tinea Imbricata.

demonstrated that the aspergillus-like fungi described by a number of authorities are merely saprophytes, and that the true ætiological agents are those fungi for which he has created the genus *Endodermophyton.*

Climatology.—The home of tinea imbricata seems to have been the Malay Peninsula, from whence it spread towards the south and the east to many islands of the South Pacific, northwards to some

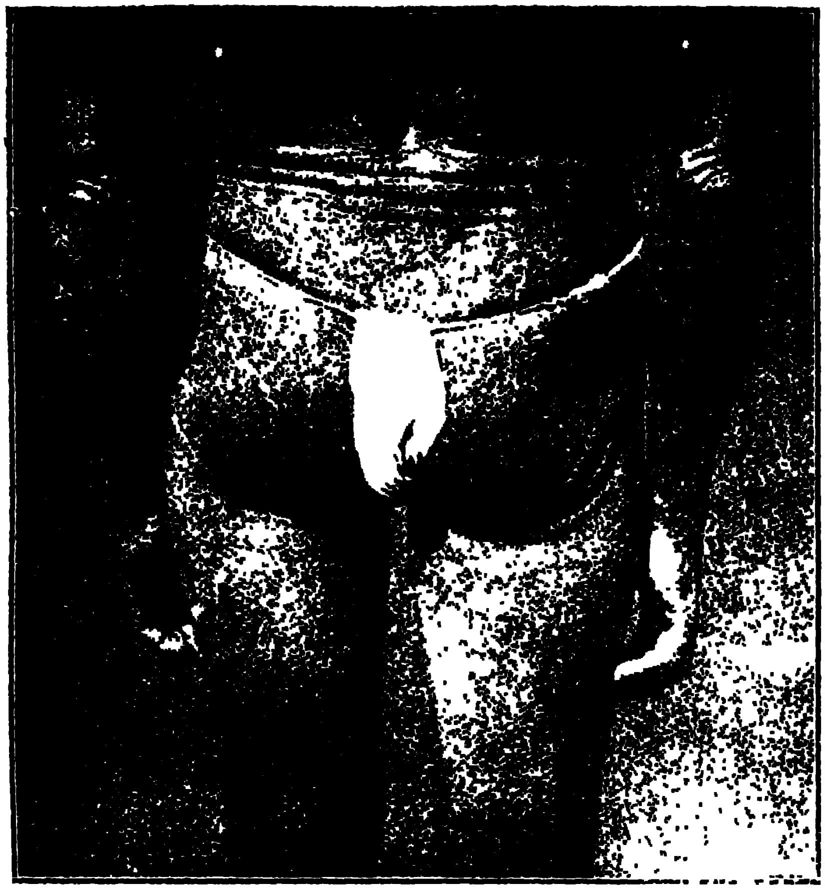

FIG. 810.—TINEA IMBRICATA.

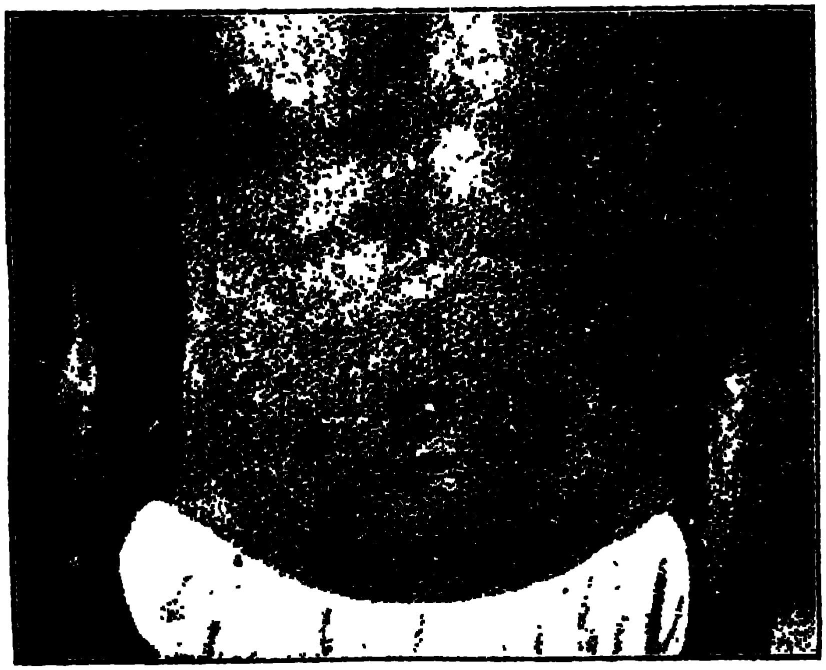

FIG. 811.—TINEA IMBRICATA.

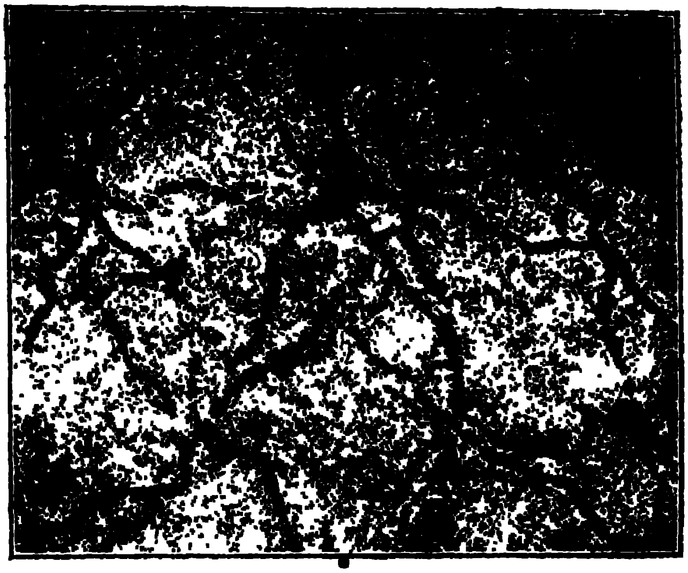

FIG. 812.—FUNGUS IN THE SCALES.
(From a stained preparation.)

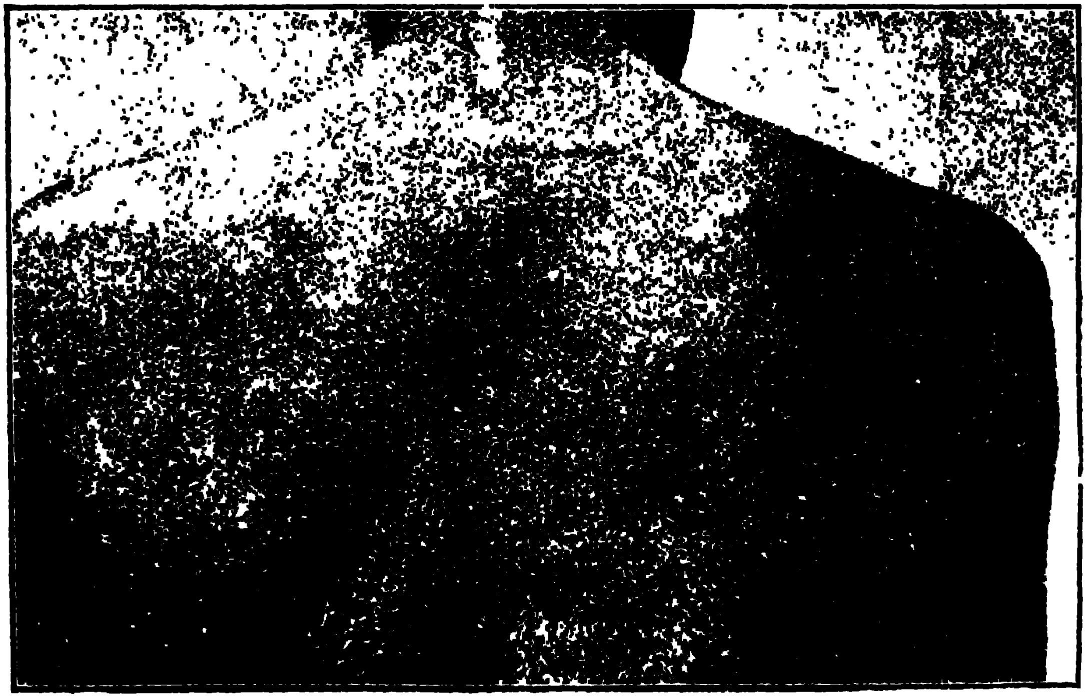

FIG. 813.—TINEA IMBRICATA.

parts of China, as far as Foochow and Formosa, and westwards to Burma and Ceylon. The Gilbert group of islands seems to have become heavily infected since the beginning of last century. In 1859 it is said that a native of Tamana, an island of the Gilbert group, affected with the malady, landed at Bowditch, an island called also Tokelau, in 1859. From that year onwards the disease spread rapidly all over the Bowditch or Tokelau Island. The Tamana man who brought the disease was called Peter, hence the disease became known in Bowditch or Tokelau as 'Le Pita' viz., 'The Peter.' From Tokelau the disease spread to Samoa, according to Turner and Königer, in 1869, and to many other islands, where it became known as Tokelau. At the present time the disease is extremely common in the Malay Peninsula, some parts of Indo-China and Southern

China, Borneo, Samoa, Java, the Solomon Islands, New Guinea, Sumatra, Fiji. According to Daniels, the disease was first introduced into Fiji by some Solomon Islanders in 1870, and within the following two years became extremely prevalent. In certain of the Pacific Islands one-third to one-half the population is affected. The disease is common in some districts of the Philippine Islands, the Ladrones, the Loyalty Islands, New Caledonia, and some districts of Burma. Until 1904 the disease was believed to be non-existent in Ceylon, but in that year Castellani recorded the first case. During the last few years the disease has greatly spread in this island, and it is now fairly common, though not so common as in the Malay Peninsula or Fiji. India is said to be so far immune, but two typical cases hailing from Southern India have been seen by Castellani. Cases have been reported from Brazil and other parts of tropical America, but some doubt has been expressed as to their being cases of true tinea imbricata. The cases so far reported from Africa are also doubtful.

FIG. 614—TINEA IMBRICATA.

The climatic conditions favourable to the rapid development and spread of the disease are represented by a warm, damp, equable climate, with a temperature of 80° to 90° F., the same climate, as Manson so truly remarks, that is favourable to the growth of cocoanuts; in fact, the geographical distribution of tinea imbricata corresponds almost exactly to the districts where cocoanuts thrive. In those countries which, though at certain times extremely hot, have a cold and cool season—such as many parts of India and China—the disease apparently does not spread.

Ætiology.—The ætiology of this dermatomycosis has been the subject of numerous controversies. Manson first, in 1872, described a trichophyton-like organism in the squamæ; with the laboratory technique of that time attempts at cultivation did not succeed. Blanchard considered it non-cultivable, and called it '*Trichophyton concentricum*'; on the other hand, Nieuwenhuis stated that it was quite easily cultivated direct on solid media from the squamæ, and was characterized by the colonies being crateriform. His results were not confirmed. In recent years the general opinion has been that aspergillus-like fungi were the real cause of the disease. Tribondeau described fructifications somewhat similar to those of an aspergillus, and created for the fungus the genus *Lepidophyton* (λέπις=scale; φυτόν=plant). Wehmer has described it as a true aspergillus—*Aspergillus tokelau*. The investigations carried out by Castellani have demonstrated that the aspergillus and aspergillus-like fungi have nothing to do with the disease. When they are present in the squamæ, they are merely saprophytes or contaminations. By using a special technique he has succeeded in growing the true fungi causing the disease, which must be placed in the genus *Endodermophyton*. Castellani recognized at first two species, and later four: *Endodermophyton indicum*, *Endodermophyton tropicale*, *Endodermophyton concentricum*, and *Endodermophyton mansoni*. It is probable that further investigation will reveal the existence of some more species. The description of these fungi will be found in Chapter XXXVIII., p. 1016.

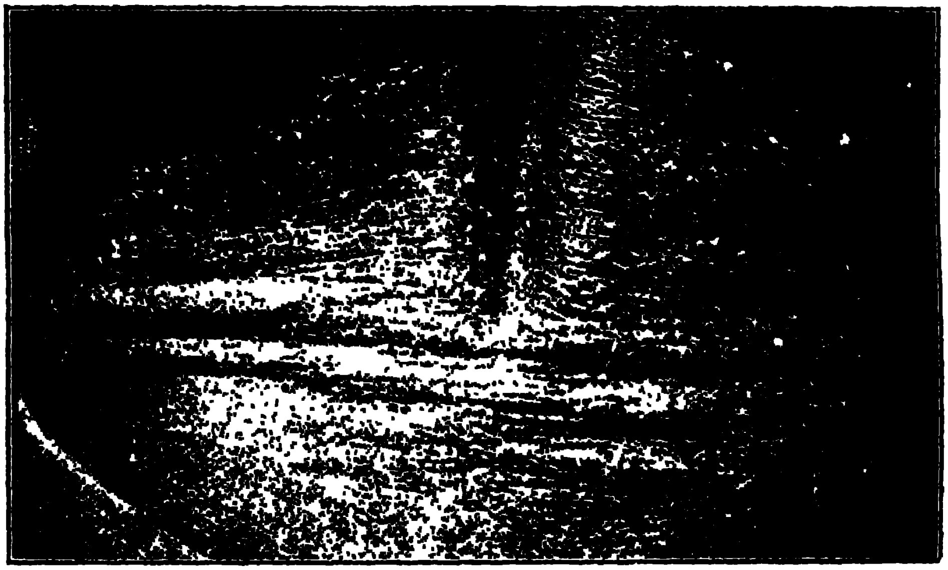

FIG. 815.—TINEA IMBRICATA.

Predisposing Causes.—As regards age, many authorities state that the disease is more common in children than in adults. In Ceylon, however, the condition is rare or absent in infants and children, while the persons affected are generally young adults, but it may be found also in very old persons. Women are attacked less frequently than men. Villagers and people living in the country are much more liable to contract the malady than people living in large towns. It is doubtful whether there is any racial disposition. In Fiji, however, it has been observed that while extremely common in the indigenous population, it is comparatively rare among the immigrant Indian coolies. The Tongans also are said to contract the disease rarely, and this relative immunity, according to them, is due to the habit they have of regularly anointing their bodies—a habit not shared by the Fijians. A hot, moist, equable climate seems to be the most suitable for the development of the fungus and the spreading of the disease. Manson has justly remarked that the climate which is suitable for the growth of cocoanuts is also the best for the fungus of tinea imbricata.

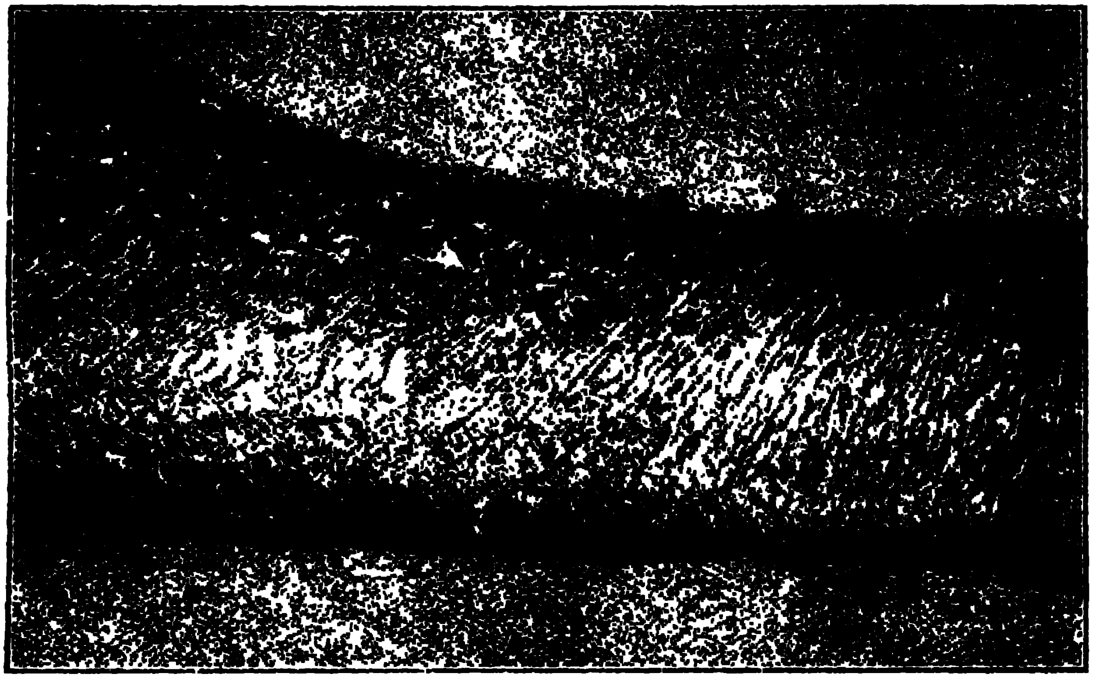

FIG. 816.—TINEA IMBRICATA OF THE FOREARM (OLD CASE).

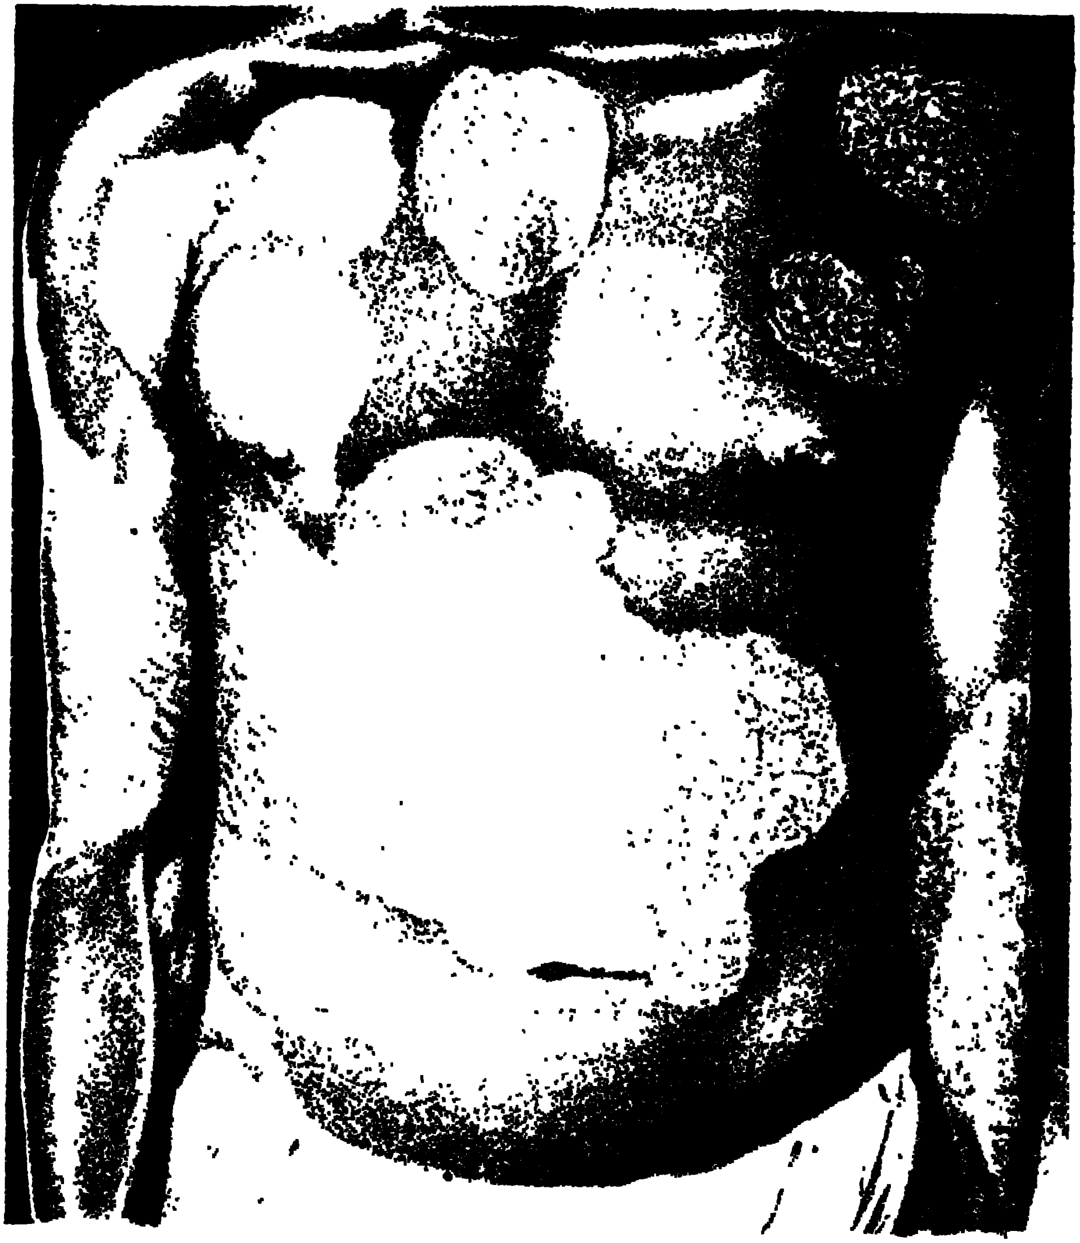
Symptomatology.—The eruption begins with one or several small, roundish or oval, slightly raised, dark brownish patches, very itching. Soon the central portion of each patch splits, and a ring of flaky large scales attached at the periphery is formed. This scaly ring extends peripherally, and in the meantime another brownish patch appears in the centre at the site of the first brown spot: the new brownish patch breaks, and a second scaly ring is formed, which extends peripherically inside the first ring, and so on until a very large roundish patch is formed, containing several concentric scaly rings. Manson has aptly compared this formation of rings to concentric ripples

PLATE X.



TINEA IMBRICATA

[illegible]

To face page [illegible]

produced by a stone thrown into a pool of water, and when the eruption starts from many points, as is often the case owing to auto-infection, it is as if a shower of stones had fallen in the pond, and many systems of spreading rings are produced which intersect each other in various directions, and give rise to a more complex pattern. The patches extend at the rate of a quarter to half an inch a week. In a well-marked, advanced case of the disease the skin of practically the whole body is covered with round patches, each of which presents several concentric, not inflamed, scaly rings. The scales are flaky, resembling tissue paper, of large size—up to half an inch in length—dry, of a dirty greyish or brownish colour, and slightly curled. The largest scales are generally found on the back. Each scale has a free border, and is firmly attached by the opposite side; the free border of each scale is towards the centre of the circle, while the attached border is towards the periphery. If the scales are removed, rings of concentric circular dark lines remain visible, a quarter to half an inch apart. The number of rings forming the patch varies; as many as eight and ten may be present in the same patch. The eruption may spread to any part of the body except the scalp. Though several authors state that the eruption never affects the face or axilla, and rarely the palms and soles, it is often observed in such situations. The nails may be affected and become much thickened, with rough surface and deep cracks. Scrapings examined in liq. potassæ show the fungus. The fungus never invades the hair follicles. The general health is not much affected, but the patients complain of the disfigurement and of the unbearable pruritus. The pruritus greatly increases apparently if the patient is given certain diets—for instance, dry-fish diet. In the hot season the pruritus is

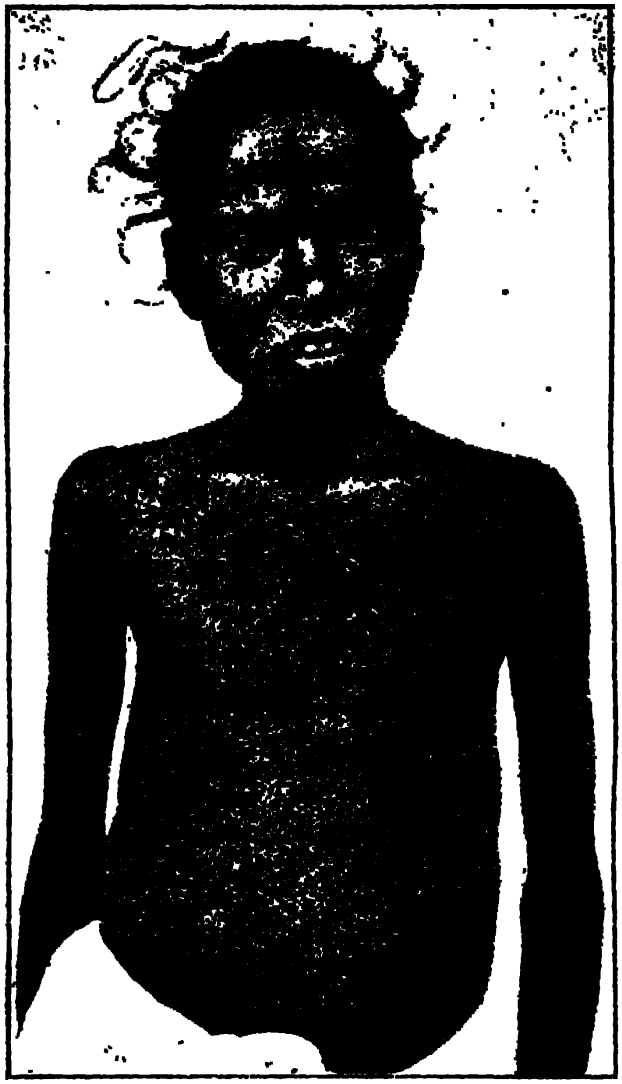


FIG. 817.—TINEA IMBRICATA.

much more marked. The disease is very chronic and very difficult to cure. In many cases the blood shows a certain degree of eosinophilia, the number of eosinophile leucocytes varying between 6 and 16 per cent. In some cases the eosinophilia is probably due to the presence of intestinal worms; the eosinophilia is, however, observed also in some cases in which the microscopical examination of the fæces does not show any ova of worms. In very old cases the eosinophilia is more marked than in recent ones, and signs of anæmia may be present.

Clinical Varieties.—The eruption may after a time or from the very beginning have a diffuse appearance instead of that of concentric rings. The scales, however, are typical and identical to those found in the concentric type—viz., they are large, tissue-paper-like, partially covering each other like tiles on a roof, and most of them firmly adherent by their bases. One variety* of the disease is characterized by the facility with which extensive pieces of epidermis can be stripped off—a condition almost comparable to moulting.

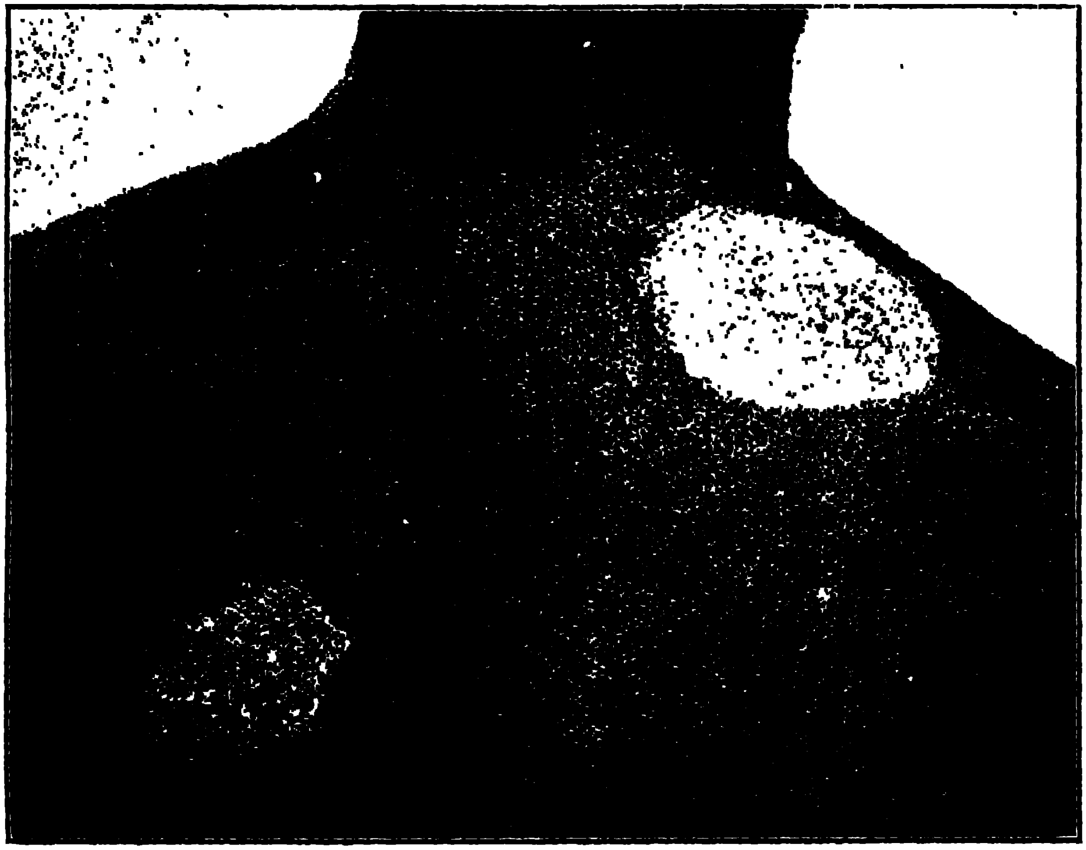

FIG. 818.—EXPERIMENTAL TINEA IMBRICATA OBTAINED BY INOCULATING CULTURES OF *Endodermophyton tropicale*.

The same fungus—viz., either *Endodermophyton tropicale* or *E. indicum*—may give rise at times to the concentric type, at other times to the diffuse type. In some cases the lesions caused by *E. indicum* seem to be slightly different from those given by *E. tropicale*, the lesions caused by the former being perhaps a little more superficial and the scales not situated so close together. Further researches will probably show that there are several other species of Endodermophytons, each of which will probably give rise to a slightly different type of the disease.

Experimental Reproduction of the Disease.—The disease is easily reproduced in human beings by inoculating scales, as was done by Manson, or pure cultures of the fungi, as done by Castellani. The incubation period by the first procedure is eight to ten days. By inoculating cultures of the fungi the incubation period is generally somewhat longer (twelve to twenty days), but the eruption develops typically. It is of interest to note that if very old cultures are used instead of young ones the inoculation may fail completely, or merely an evanescent, superficial, papuloid, trichophytic-like patch may be induced.

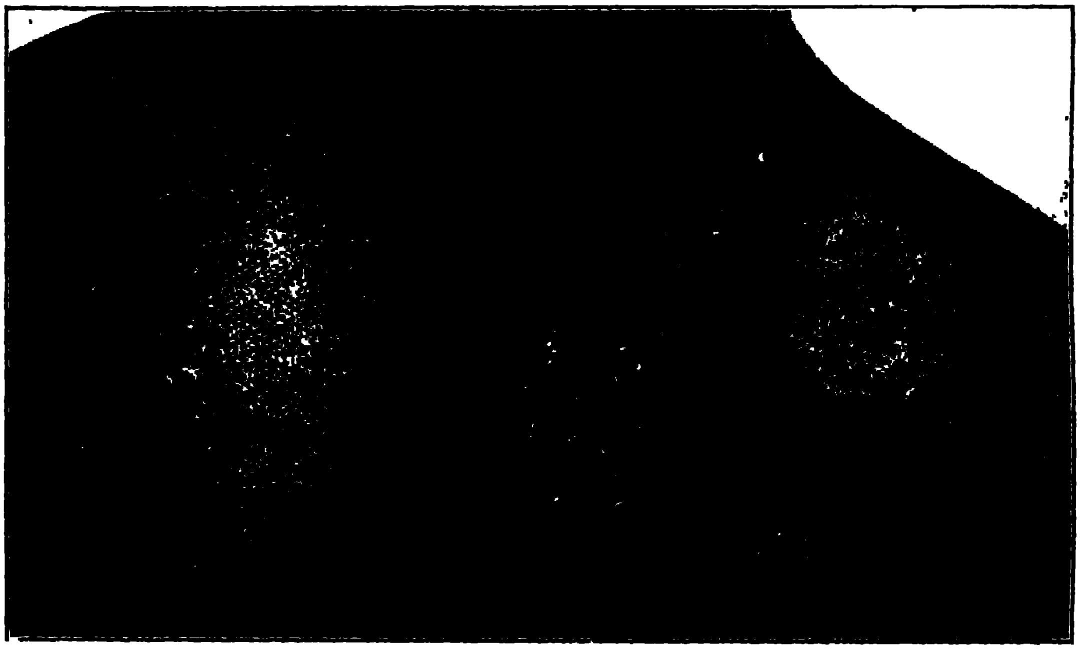

FIG. 819.—EXPERIMENTAL TINEA IMBRICATA OBTAINED BY INOCULATING CULTURES OF *Endodermophyton indicum*.

Compare with Fig. 818. Note the different clinical appearance from experimental tinea imbricata induced by *Endodermophyton tropicale*.

Diagnosis.—This is easy, the presence of concentric rings fringed with large tissue-paper-like scales being characteristic. Even when the concentric rings are not present and the eruption is diffuse the diagnosis is not difficult, being based on the characteristic large, dry, tissue-paper-like scales, overlapping each other like tiles on a roof, and containing under microscopical examination an enormous amount of interlacing mycelial tubes.

Differential Diagnosis—*Ringworm.*—Tinea imbricata has an absolutely different clinical aspect from any type of body ringworm; inflammatory signs are totally absent, and the scales are very large, flaky, firmly attached by their bases, and arranged in parallel lines or concentric circles. The scales contain an enormous amount of the fungus.

Ichthyosis.—The medical man newly arrived in the tropics often mistakes the disease—when of the diffuse type—for ichthyosis, so much so that it has also received the name of tropical ichthyosis. The microscopical examination of the scales will clear the diagnosis at once.

Pityriasis rubra.—In tinea imbricata there is not the intense hyperæmia of the skin, and the scales are firmly attached. The microscopical examination will clear the diagnosis in any doubtful case.

Tinea intersecta. Tinea intersecta begins in a manner somewhat similar to tinea imbricata, dark-brownish patches being present at first, and the fungus in both eruptions growing between the superficial and deep strata of the epidermis. In contrast to tinea imbricata, however, the eruption never develops in concentric rings, the scales are not firmly attached, and the cure is easy.

Prognosis.—The disease has no tendency to spontaneous cure, and the treatment is difficult. The general health is not much affected, but the patient complains of the disfigurement, which is very great, and of the pruritus, which in the hot season may be unbearable. Europeans complain also of pain, especially if the fungus attacks the hands. In very chronic cases signs of anæmia, general weakness, and emaciation may appear. Coolies affected with the malady in an advanced stage are unable to work owing to the extreme pruritus; hence the disease is of great economical importance, as it may greatly decrease the supply of labour on estates, etc.

Treatment.—Every medical man practising in the tropics well knows how difficult is the treatment of tinea imbricata. It is easy to obtain a temporary improvement, and even a disappearance of the eruption; but as soon as the treatment is discontinued the eruption, as a rule, starts afresh.

Strong iodine liniment, as recommended by Manson, or resorcin dissolved in tincture of benzoin (resorcin. ʒii.; tr. benz. co., ℥i.), as recommended by Castellani, or chrysarobin ointment (5 per cent.) give, on the whole, the best results.

In the Colombo Clinic of Tropical Medicine one of us made various experiments to test the efficacy of the various medicaments by applying simultaneously different liniments, ointments, etc., to symmetrical parts of the body, and comparing the result. According to his results:—

Sulphur has practically no effect whatever on the fungus.

Turpentine generally induces a slight improvement, some scales disappearing, and the skin becoming smoother; the improvement, however, is not permanent, and as soon as the turpentine application is discontinued the typical scales reappear.

Calomel and other ointments of mercurial preparations do not induce any improvement in the eruption.

Thymol and *Naphthol* ointments may cause a slight improvement.

Carbolic Acid and *Epicarin* ointments have no effect whatever.

Cyllin ointment (20 to 50 per cent.) may induce a temporary improvement.

Formalin is very effective for localized patches. The usual 40 per cent. solution is applied with care, treating each time a small portion of the eruption. Formalin often causes severe pain and a certain degree of inflammation, which is best relieved by applications of iced water. Soon after the application of formalin the patches become dark brownish, which colour lasts for a few days, when they clear. Care must be taken not to apply the formalin to too large portions of the skin, and not to repeat the application too often; otherwise a peculiar form of apigmentation, similar to leucodermic patches, may appear later on, to which disfigurement coloured patients strongly object.

Chrysarobin.—The repeated application of chrysarobin ointment (30 grains to 1 ounce of vaseline) may induce a strikingly rapid improvement in cases which are not of long standing. The eruption, however, recommences a few days or weeks after its apparent disappearance. Chrysarobin is a very toxic medicament; the patient must be watched and the urine regularly examined. In one of our cases symptoms of absorption appeared after a single application.

Salicylic Acid and *Methyl Salicylate* have very little, if any, action on the fungus.

Tinctura Iodi and Linimentum Iodi.—Tinctura iodi, freely applied, induces a very marked improvement, which, however, is not permanent. Strong iodine liniment, as recommended by Manson, is most effective; it cannot be used freely, however, on patients with a delicate skin, such as women and children.

Resorcin and Tincture of Benzoin.—Resorcin, alone or mixed with salicylic acid in alcoholic solution and in ointments, has very little efficacy. If, however, resorcin be dissolved in tinctura benzoini composita (60 to 120 grains of resorcin to 1 ounce of the tincture of benzoin), very good results are obtained; it is now the routine treatment for tinea imbricata in the Colombo Clinic. It is to be noted that tincture of benzoin without resorcin has very little action on the eruption. The resorcin, dissolved in tincture of benzoin, should be applied freely once or twice daily on the affected regions. If the whole body be affected, one day one half is painted, and the other days the other half, alternately. The treatment must be continued for several weeks. Once or twice a week the patient is given a very hot bath, and scrubbed all over with sand-soap. Symptoms of absorption are rare; it is always prudent, however, to proceed at first with care, as it is well known that individuals may be met with, though rarely, showing idiosyncrasy for resorcin.

Prophylaxis.—Some authorities recommend isolation: this is good wherever possible, but in regions where the disease is or has become endemic usually the great number of people suffering from the affection render the measure hardly practicable. In those tropical countries, however, where the disease has not yet appeared, the medical officers would do well to be on the look-out for it, and if a case is reported the patient should certainly be kept isolated and thoroughly treated before being allowed to mix with the general population, and all infected clothing should be boiled or burnt. We have seen an epidemic of tinea imbricata in a hospital in which a patient suffering from the disease was admitted and allowed to mix with the other patients. There is a general native belief that anointing the body with cocoanut oil or other oil will prevent infection; there may be some truth in the belief, but such a measure cannot be carried out in Europeans. Any itchy, scaly spot in the slightest way suspicious of incipient tinea imbricata should be immediately treated with lin. iodi, chrysarobin ointment, or resorcin dissolved in tr. benzoini. While the treatment of tinea imbricata in an advanced stage is extremely difficult, it is easy to stop the initial patches by these means.

TINEA INTERSECTA (*vide* Plate XI.).

This dermatomycosis and its fungus were first described by Castellani in 1907. It occurs in Ceylon and Southern India.

Ætiology.—If a portion of one of the brown patches or a scale be removed and treated with liquor potassæ, the fungus is easily detected. The fungus (*Endodermophyton castellanii* Perry, 1907) grows between the superficial and the deep strata of the epidermis. It is present on the inner surface of the scales, but not on the external surface. A very remarkable fact is the extreme rarity of free spores; in fact, in several cases one does not succeed in finding spores. The mycelium is fairly abundant, though far from being so abundant as in tinea imbricata. It is composed of long, straight articulated threads, which are sometimes dichotomous, the breadth being between 3 and 3½ μ. Each segment presents in fresh preparation two refractile bodies, one at each extremity. No aspergillar fructifications nor clusters of spores are seen. Attempts at growing the fungus have succeeded only in one case, the growth being somewhat similar to that of *Endodermophyton indicum* Castellani (p. 1020).

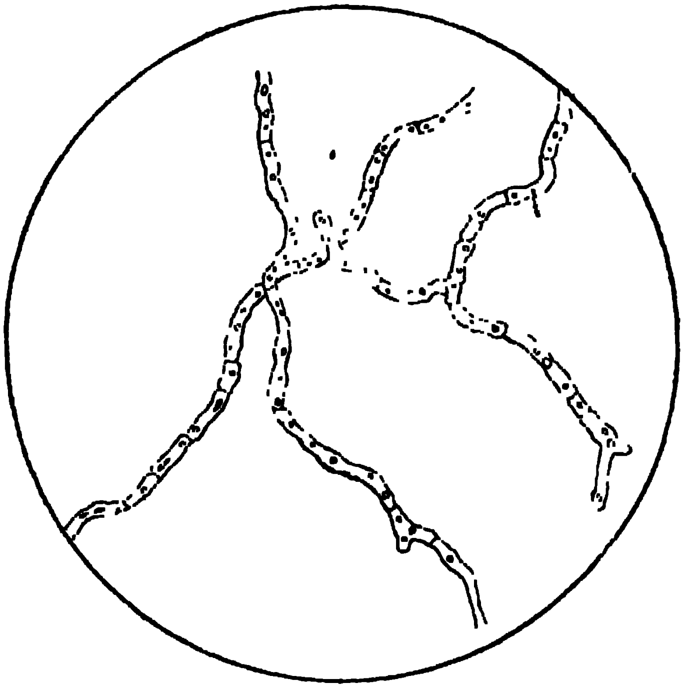

FIG 820.—FUNGUS OF TINEA INTERSECTA (From a scale in liq. potassæ.)

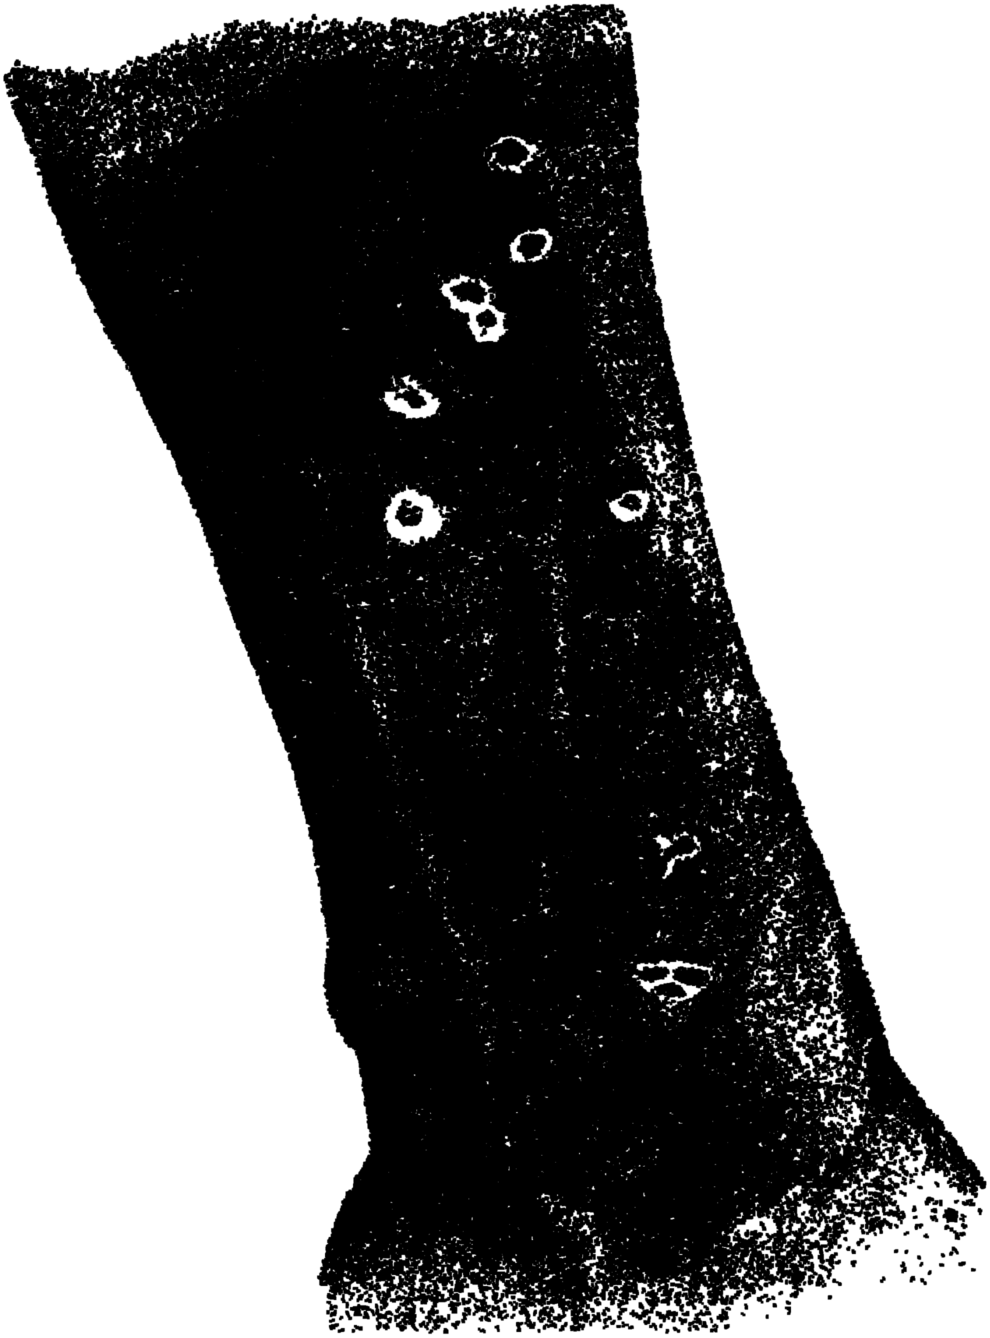
Symptomatology.—The eruption begins with small oval or roundish, very slightly elevated itching patches, generally situated on the arms, legs, chest, and back. The margins of these dark spots are at first slightly elevated, and dotted often with minute dark papules. The patches are dark brown in colour, much darker

PLATE XI.



LINEA INTERSECTA (KROMAYER)

[illegible]

than the surrounding skin, and presents a smooth, tense surface at first; they increase in size slowly, and some coalesce. After a certain time the surface of the patches is no longer tense; it becomes somewhat shrivelled and dry; superficial cracks appear in it, so that white lines are visible intersecting the brown surface. Later the cracks become deeper, the epidermis splits, and several flaky, curled-up scales, whitish inside and dark on the outer surface, are seen; the scales are often removed by friction, and whitish roundish patches only remain. The eruption never develops in concentric rings like tinea imbricata; the patches remain isolated or fuse together, forming irregular larger patches. Some patches may disappear spontaneously after a time. The general health of the patient does not seem to be affected. In some patients there is a slight degree of eosinophilia.

Diagnosis.—When the eruption is in the very first stage it might be mistaken for a form of pityriasis versicolor. In pityriasis versicolor, however, the epidermis does not split: moreover, in tinea intersecta the fungus is not found on the surface: it grows between the superficial and deep layers of the epidermis. Tinea imbricata begins in a manner somewhat similar to tinea intersecta, dark brownish patches being present, and the fungus in both eruptions growing between the superficial and deep layers of the epidermis. In contrast to tinea imbricata, however, the eruption of tinea intersecta never develops in concentric rings: is far less severe, as patches may heal spontaneously; and is cured without much difficulty.

Treatment.—Tincture of iodine and the usual antiseptic ointments, such as chrysarobin (2 to 5 per cent.), answer well.

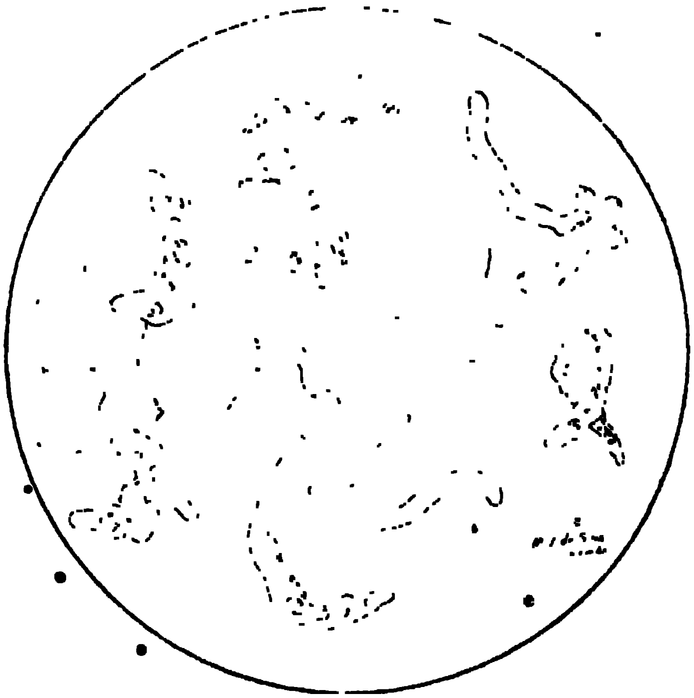


FIG. 821.—FUNGUS OF TINEA FLAVA (OLD CASE). (From a specimen stained by the Morris-Walker method.)

TINEA FLAVA

(*vide* Plate XII.).

Synonyms.—Tropical Pityriasis Versicolor of the old authors, Microsporosis Flava (Castellani), Achromie Parasitaire (Jeanselme), Pityriasis Versicolor Flava (Castellani), Achromia Squamosa (Crocker).

This dermatomycosis is extremely common in all tropical countries, and especially so in Southern India, Ceylon, Malaya, Java, Indo-China, and China. By many authors it has been, and is still, confused with the ordinary pityriasis vesicolor of temperate zones; the investigations of Castellani and Jeanselme, however, have clearly proved that it is a different affection.

Ætiology.—The affection is due to *Malassezia tropica* Castellani, 1905. The mycelial threads are generally thick, with numerous swellings, constrictions, and other irregularities in their shape. The spores are roundish or oval (3·50 to 4·50 μ), and have a double contour. In recent cases the fungus is abundant, with plenty of mycelium and spores which often run into clusters. In old chronic patches the fungus becomes very scanty; the spores are not numerous, and generally do not collect in clusters; the mycelium is very scanty, and is even more irregular in shape than it is in recent patches (degeneration forms of the fungus). For full description of the fungus see p. 1099.

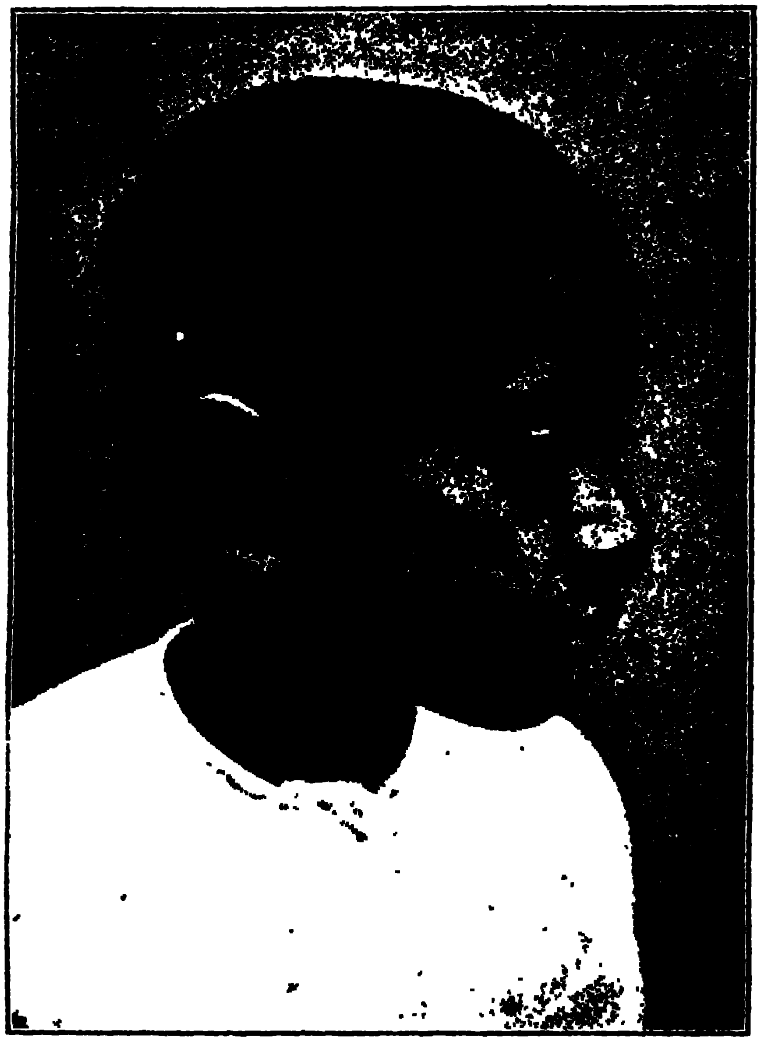

FIG. 822 – TINEA FLAVA ON THE FACE OF A SINHALESE.

Symptomatology.—The affected parts are yellowish, of much lighter colour than the surrounding healthy skin; the yellow colour may be of various tinges, from dark, deep orange-yellow in some cases to very light canary-yellow in others. The patches are of

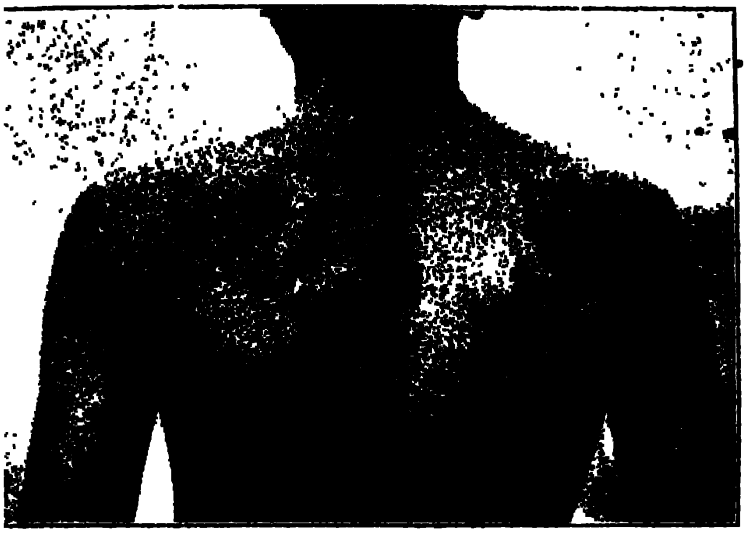

FIG. 823.—TINEA FLAVA ON THE BACK.

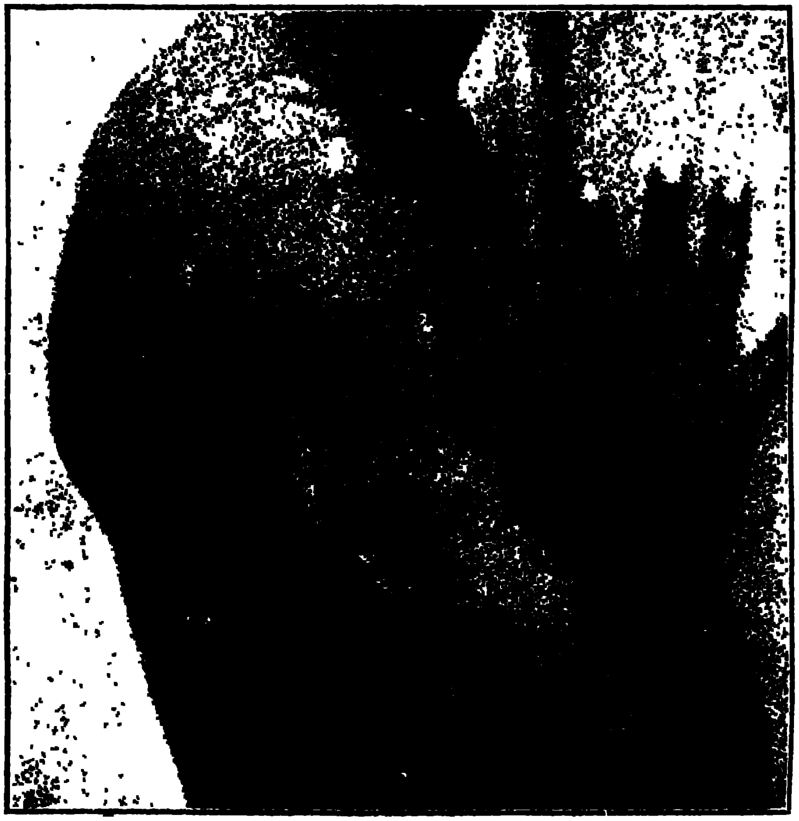

FIG. 824.—TINEA FLAVA OF THE ARM.

various sizes, generally roundish, smooth, sharply defined, with margins not elevated, or only slightly so. Sometimes the patches are irregularly festooned, and may encircle an area of healthy skin. Occasionally the encircled healthy skin appears to be intersected by many yellowish, ribbon-like lines originating from the surrounding yellow patch. The regions more frequently affected are, in order of frequency, the face, neck, chest, and abdomen. Large portions of the body may be involved. There is, as a rule, no pruritus. The patches are not desquamating, or only very slightly so. The course of tinea flava is very chronic. In the natives of the lower classes it appears in childhood in the shape of tiny spots on the face and chest, spreading slowly during years; they may coalesce, covering practically the whole of the face and chest.

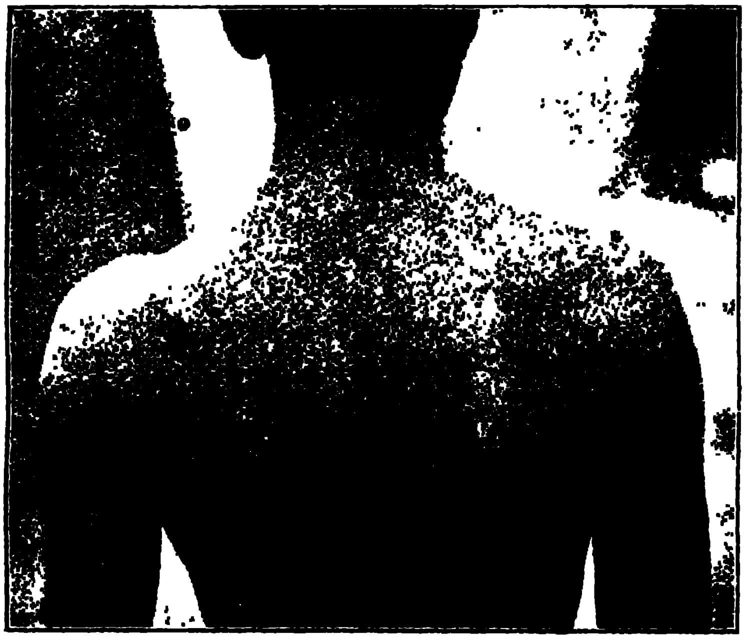

FIG. 825.—TINEA FLAVA: VARIETY GUTTATA.

One is occasionally surprised to see a native whose face and chest are quite light in colour; on closer examination, it may be found that this lighter appearance is due to a diffuse, very light-coloured form of tinea flava, covering the whole of the face, neck, and chest. In Ceylonese native women, when the patches of tinea flava are small, light, and situated on the face, they are considered to be beauty-spots, and are highly appreciated by the ladies and their admirers. Such patches are called in Sinhalese 'alu-hama,' which means ashy skin (*alu*, ash; *hama*, skin). There is also another word used by native poets for such condition—'gomera,' which means skin dotted with beauty-spots. The disease, which is extremely common, attacks mostly natives, but occasionally Europeans also. In Europeans the patches are yellowish-reddish or pinkish (tinea rosea), and may be due to different strains of *M. tropica*.

Prognosis.—The disease is very chronic and has no tendency whatever to spontaneous cure, but the general health is not affected.

Diagnosis.—*Pityriasis versicolor* of temperate zones is not of so light a tinge as tinea flava, never attacks the face, and is curable with the greatest facility; while tinea flava affects the face more frequently than any other part of the body, and is curable only with difficulty.

Tinea Alba.—Occasionally there may be some difficulty in distinguishing tinea flava of a light variety from tinea alba. In contrast to tinea flava, the patches of tinea alba are not smooth, and the fungi belong to the genera *Trichophyton* and *Epidermophyton*.

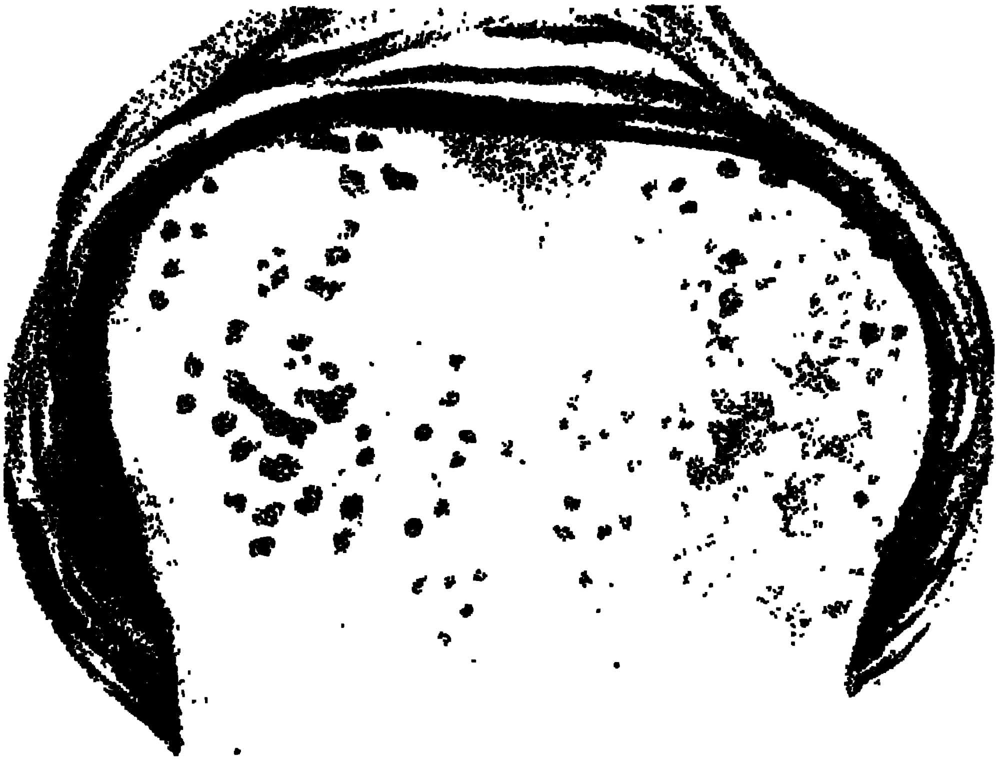

FIG. 826.—TINEA FLAVA ON THE BACK OF A EUROPEAN.

Tinea Flava and *Pinta* are easily distinguished by the characters of their respective fungi, the fungus found in pinta never having the characters of a *Malassezia*.

Leucoderma patches have a characteristic dead-white colour, are often surrounded by a hyperpigmented border, and no fungus is found.

In *Circumscribed Scleroderma* (Morphœa) the patches may present a peculiar yellowish tinge, which in coloured patients may resemble tinea flava. In tinea flava, however, there is no change in the texture of the skin, which is still pliable, and does not exhibit the peculiar parchment-like feeling of scleroderma. The microscopical examination will clear the diagnosis in any doubtful-case.

In Europeans, tinea flava, taking often a reddish colour (hence the term 'tinea rosea'), especially if the patient has been exerting himself and is perspiring, might, on superficial examination, be mistaken for a form of *Seborrhœa corporis.* The microscopical examination will clear the diagnosis, no *Malassezia* fungus being found in seborrhœa corporis.

Treatment.—Tinea flava shows no tendency to spontaneous cure unless the patient moves to a cold climate. Even then, very often the cure is only apparent, as the condition reappears during the hot weather. The treatment is difficult. Turpentine applied daily, followed by a naphthol or epicarin ointment (2 to 5 per cent.), or a salicylic-resorcin ointment (resorcin ʒi., acidi salicyli gr. x., vaselini ℥i.), is often successful, but the treatment must be continued for months. On covered parts of the body tincture of iodine may be used, or a chrysarobin ointment (2 per cent.).

It is to be noted that in several cases the fungus of tinea flava has apparently a deep permanent disturbing action on the pigmentation processes of the skin, as, even when the fungus has been destroyed, the patches may remain of a lighter colour than the surrounding skin for a long time, though ultimately they become again normally pigmented.

TINEA NIGRA.

Synonyms.—Pityriasis Nigra (Castellani), Microsporosis Nigra (Castellani).

This affection is fairly common in India, Ceylon, Java, Federated Malay States, and China. The first account of this, or a very similar, dermatomycosis was published by Manson in China in 1872. Manson's observations, however, were forgotten, as they were not quoted by him in his subsequent works. Castellani, in 1905, redescribed the disease in Ceylon, and succeeded in growing the fungus.

Ætiology.—The affection is caused by a fungus of the genus *Cladosporium*—*C. mansoni* Castellani, 1905. The fungus is found very abundantly in the lesions; the mycelial elements are rather short—18 to 20 μ in length, and 2½ to 3½ μ in breadth. Sometimes they may be irregular in outline, bent, banana-shaped. The spores are globular, and most of them very large—5 to 8 μ. They are frequently arranged in clusters.

The fungus is easily cultivated by inoculating scrapings of the affected patches on maltose agar. After two to four days roundish hemispheric colonies appear, which are black, but at first have usually a greenish tinge, and may present at the periphery some radiating, delicate, pale greenish hyphæ. These colonies may remain separate or more often gradually coalesce into a jet-black knobby mass, deeply rooted into the medium.

The fungus grows well, though less abundantly, on the other sugar agars, and also on ordinary agar. In *broth* and *peptone-water* the growth is very

PLATE XII.

TINEA FLAVA ON THE FACE AND
TINEA NIGRA ON THE NECK.

Geo. Waterston & Sons Ltd Edin

To face page 23

slow, and takes place at the bottom of the tubes, with formation of a black or greenish-black sediment.

The *optimum temperature* for the growth of the fungus is betwen 30° and 32° C.; above 35° C. and under 25° C. the growth is much slower, and may be nil under 20° C. Further details on the fungus may be found on p. 1100.

Symptomatology.—The affected parts are of a black, dull, lustreless colour, much darker than the surrounding dark, healthy skin of the native. The patches may be small, roundish, and separated from one another, or may coalesce; the patches are often slightly elevated, and may present a slight desquamation. Little, if any, pruritus is present. The face is not usually affected, though the eruption may be found on practically any other region of the body. The neck and upper portion of the chest are apparently the regions most frequently affected. Tinea nigra usually attacks natives. We have, however, seen it also in one of our European patients, who went for a pleasure trip to Burma, where he remained about a month. On coming back to Ceylon, he noticed a small, roundish, very slightly elevated, non-desquamating, black patch on the palm of his left hand. There was no pruritus. The patch spread slowly for two months, reaching the size of a sixpenny-piece. It disappeared after a single application of formalin; three months later it reappeared in the same place as a tiny black dot, which slowly spread. Another application of formalin caused it to again disappear. From the patch a fungus was grown identical with the one found in native cases.

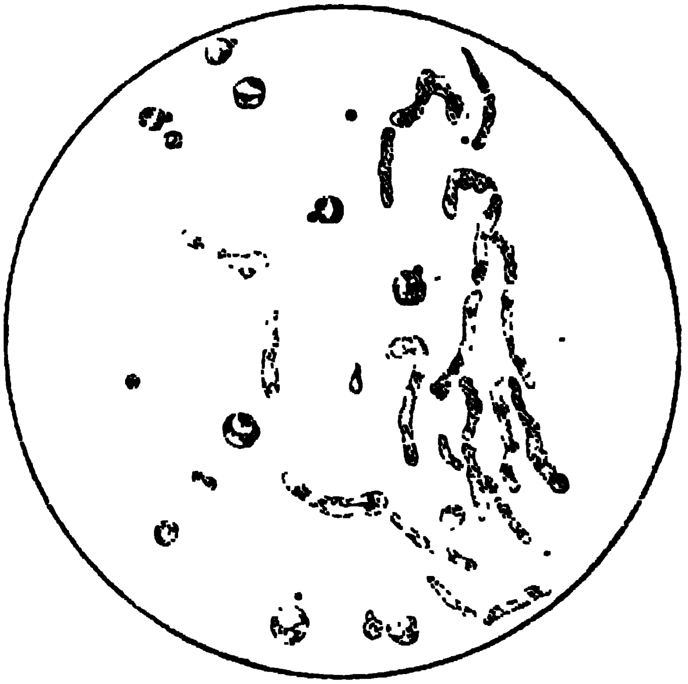

FIG. 827.—FUNGUS OF TINEA NIGRA.

Mixed Infections.—A mixed infection of tinea nigra and tinea flava is somewhat frequently met with. Several of our patients had on the neck a few round patches of tinea nigra, and on the face some smooth, yellow, roundish patches of tinea flava.

Diagnosis.—The characters of the fungus, and the fact that the disease is easily curable, readily distinguish tinea nigra from pinta. Pityriasis versicolor is generally of lighter colour than tinea nigra, and the fungus (*Malassezia versicolor*) is morphologically very different, and cannot be grown. In chloasma bronzinum no fungus is found.

Treatment.—The disease is easily curable, except when it attacks the palms of the hands, where the treatment must be more prolonged. A salicylic-alcoholic lotion (2 per cent.), followed by a resorcin ointment (resorcin, ʒi.; vaseline, ℥i.), answers well. When the patches are small, pure formalin may be used with care.

ERYTHRASMA.

This affection is frequently met with in the tropics, and is common on the continent of Europe, though apparently rare in America.

Ætiology.—It is caused by a fungus discovered by **Burchardt** in 1859—*Nocardia minutissima* Burchardt. This hyphomycete is very delicate and slender, less than 1 μ in breadth; is found in the superficial horny layer of the affected parts. Ducrey and Reale claim to have succeeded in cultivating it, but their results have not been confirmed. The description of the fungus is found on p. 1061.

Symptomatology.—The eruption generally affects the genito-crural and axillary regions, but may occasionally spread to other parts of the body. It is characterized by the presence of brownish-reddish patches, rounded or irregularly shaped, but with well-defined borders. The borders are not elevated; the surface of the patches appears slightly furfuraceous, and has often a somewhat greasy feeling. There are no subjective symptoms, except occasionally slight itching.

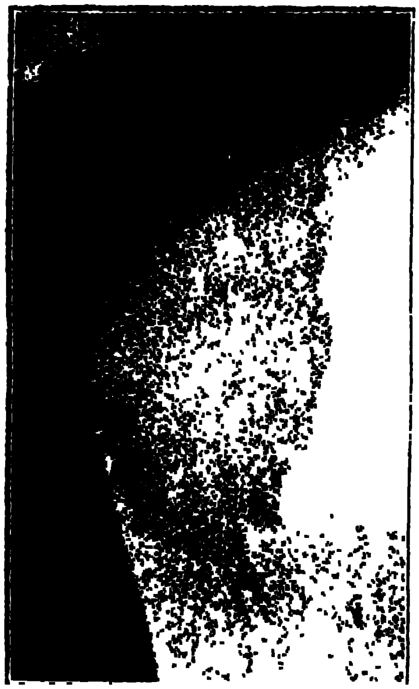

FIG. 828.—ERYTHRASMA.

Diagnosis. — Erythrasma is easily distinguished from tinea versicolor and tinea flava by the reddish tinge generally present; by the characteristic difference of its sites of development, and by the microscopical examination, which will reveal the presence of *Nocardia minutissima* Burchardt, a fungus morphologically very different from *Malassezia furfur* Robin or *M. tropica* Castellani. The differential diagnosis from tinea cruris has been discussed in this chapter under the heading Tinea Cruris (p. 2042).

As first noticed by Manson, after tinea cruris has been cured, the genito-crural region may in some cases present for years a peculiar brownish discoloration, and be slightly furfuraceous—a condition resembling erythrasma; in such cases neither *Epidermophyton cruris* Castellani nor *Nocardia minutissima* Burchardt will be found.

Treatment.—Washing the parts with ordinary soap and warm water, carbolic, tar, or sand-soap, and then regularly applying a resorcin-salicylic ointment (resorcin, gr. x. to xxx.; ac. salicyl., gr. x. to xx.; vaseline, ℥i.), will soon cause the eruption to disappear. Instead of the ointment, a hyposulphite of soda (1 drachm to 1 ounce) or sulphurous acid lotion may be used.

BLASTOMYCOSIS.

Synonyms.—Saccharomycosis Hominis, Oidiomycosis, Dermatitis Blastomycetica, Blastomycetic Dermatitis, Zymonematosis.

Definition.—The term blastomycosis covers a group of closely allied pathological conditions due to fungi of the genera *Saccharomyces*, *Cryptococcus*, *Coccidioides*, *Oidium*, and *Monilia*, generally characterized by the presence of warty patches and minute epidermal abscesses.

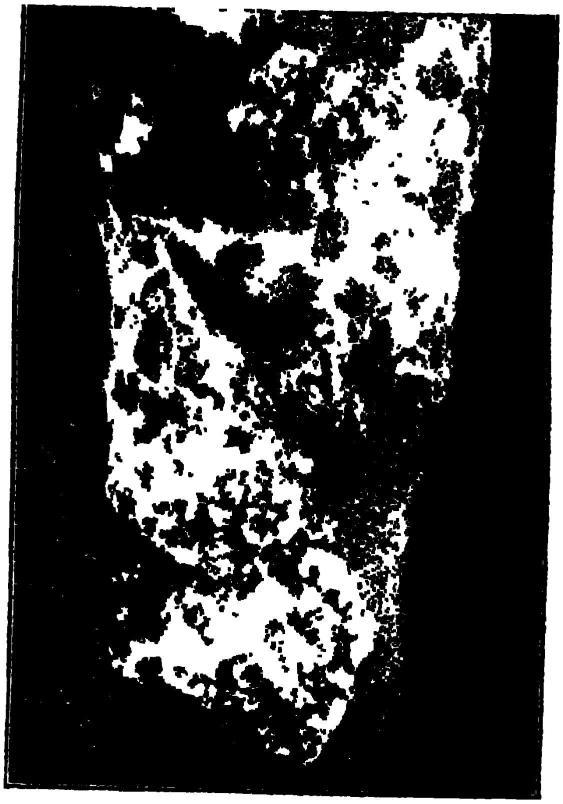

FIG. 829.—BLASTOMYCOSIS OF LEG.

Historical and Geographical.—Wernike, in 1890, described in Buenos Ayres two cases of papillomatous eruption in which he found peculiar bodies which were at first considered to be protozoa, hence the disease was called 'protozoic dermatitis.' Later Gilchrist and Ophüls showed them to be vegetal parasites. Gilchrist, in 1894, described yeast-like organisms in sections taken from a scrofuloderma-like eruption. In the same year, independently, Busse and Buschke published a case of a pyæmia-like condition due to a *Cryptococcus*. The disease has been investigated chiefly by American observers, among whom Ricketts, Ormsby, Hyde, Montgomery, and Pusey may be mentioned. The malady occurs in the tropics, and one of us has reported several cases from Ceylon, while Phalen and Nichols have described numerous cases from the Philippine Islands, Léger two cases in Tonkin, and Lutz, Splendore, and others, cases from South America.

Ætiology.—The fungi found belong to the genera *Saccharomyces*, *Cryptococcus*, *Coccidioides*, *Monilia*, including in the last-mentioned genus the following non-sufficiently defined genera: *Zymonema*, *Parasaccharomyces*, *Parendomyces*. The description of these fungi is found in Chapter XXXIX., p. 1035. There are also higher, not yet well-determined fungi, all of which are apparently capable of inducing identical clinical conditions. In the tissues all the organisms exist as yeast-like, oval, or roundish cells.

Among the organisms which cause the disease, Ricketts distinguished four types:—

1. Blastomycetoid or yeast-like type: reproduction by budding; in cultures only oval or roundish cells are seen, while mycelial tubes are as a rule absent.
2. Cryptococcus-like type: reproduction by endosporulation within the tissues.
3. Endomyces-like type: the cultures present abundant submerged mycelium, which breaks up into chains of endoconidia; proliferation by budding is rare.
4. Hyphomycetoid type: cultures present aerial hyphæ and submerged mycelium; proliferation by gemmation occasionally seen. There are many transition forms between these four groups.

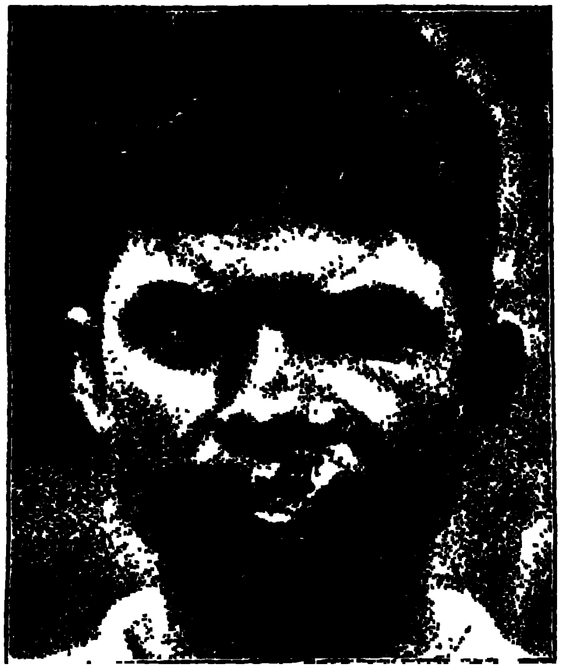

FIG. 830.—BLASTOMYCOSIS OF THE UPPER LIP: ULCERATIVE STAGE.

(From a case in the Colombo Clinic.)

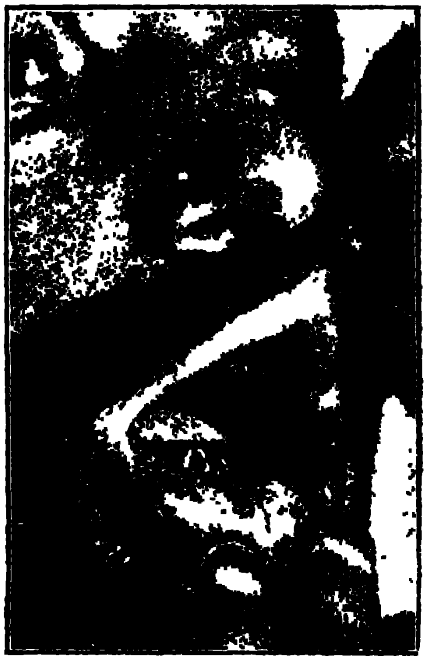

FIG. 831.—BLASTOMYCOSIS OF THE MOUTH.

(From a photograph by Splendore.)

Histopathology.—There is marked proliferation of the epithelial layers, with elongated, irregularly shaped down-growths into the corium, and epithelial globi are seen. The cells of the rete are swollen, and there is, between the cells, a polymorphonuclear leucocytic infiltration. Here and there minute miliary abscesses are present. In these, numerous polymorphonuclear and mononuclear leucocytes are found, also epithelioid cells and giant cells, some containing the parasite. It is in the miliary abscesses that the organism is mostly found. The corium presents a general cellular infiltration made up of polymorphonuclear leucocytes and young connective-tissue cells. The vessels are dilated and their walls thickened. Splendore has noted that when the lymphatic glands are affected, which is of rare occurrence, they may present histologically a tubercular appearance.

Symptomatology.—The disease, as seen by us in Ceylon, is characterized by the presence of elevated warty patches showing, especially at their margins, minute epidermal abscesses, and often small ulcers covered by yellowish crusts. The eruption may be gyrate. The lesions at a later stage may become more deeply ulcerated, the pr[illegible] ulceration generally beginning at their centre. There is very little or no pain, and very slight or no pruritus. The lesions may heal spontaneously, leaving, as a rule, soft, smooth scars. Occasionally the affection recommences after a time in the scar. The lymphatic glands are not often involved. In some cases subcutaneous abscesses and gumma-like swellings may be formed. All regions of the body may be affected. The course is very chronic, the disease lasting often for many years.

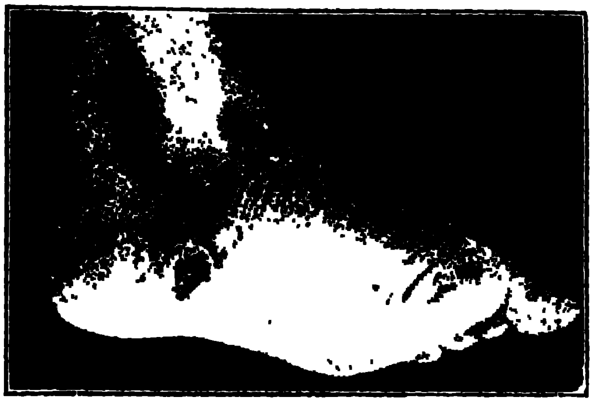

FIG. 832.—BLASTOMYCOTIC ULCER.
(From a photograph by Splendore.)

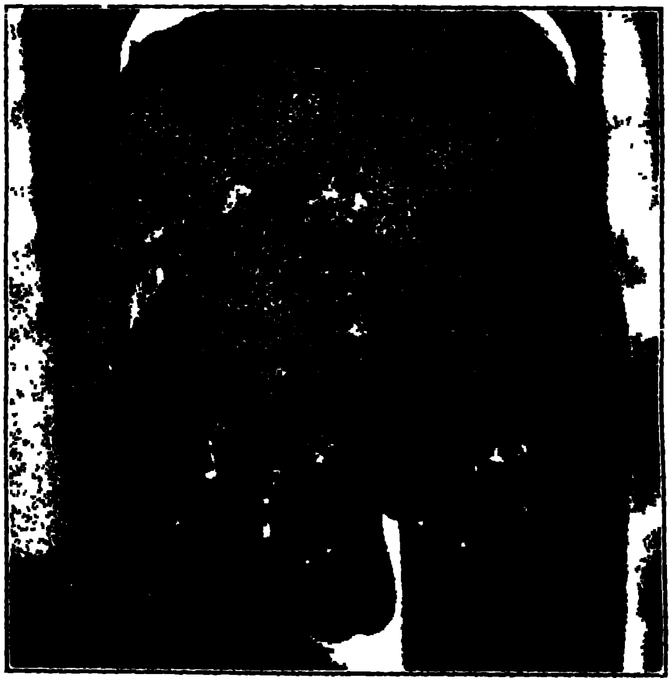

FIG. 833.—BLASTOMYCOSIS GLUTEALIS
(From a case in the Colombo Clinic.)

Clinical Varieties.—Several varieties can be distinguished:—[1]

1. The common cutaneous type, or North American and Asiatic type.
2. The oro-pharyngeal blastomycosis.
3. The Coccidioides blastomycosis.
4. The gluteal blastomycosis.

1. *Common Cutaneous Type.*—The description we have given of the disease refers to this type, which is quite common in Ceylon, Southern India, Philippine Islands, Indo-China, Tonkin, and probably in many other parts of the tropics. A very frequent localization in Ceylon is the upper lip (see Fig. 830), the disease extending later occasionally to the nasal mucosa, and very rarely to the oral mucosa. In several of our cases a monilia-like fungus was grown.

2. *Oral Blastomycosis.*- This variety has been investigated by Lutz and Splendore in South America. Splendore considers the fungus to be a *Zymonema*, and calls the disease zymonematosis. As most authorities do not accept the genus *Zymonema*, we place the fungus in the genus *Monilia* (see p. 1079). The skin lesions are identical with those found in the common type of the malady, but the infection spreads to the oral mucosa, lips, gums, soft and hard palate, giving rise to numerous small, verrucoid, papillomatous, or framboesiform patches, which later may undergo deep ulceration. The disease later invades the pharynx, nose, larynx, and bronchi, and often terminates fatally.

3. *Blastomycosis Coccidioides* (synonym, Protozoic disease) was described by Wernike of Buenos Ayres in 1890, and later by Posadas; it was further investigated by Ophüls, Moffit, and others. It was at first considered to be of protozoal origin. The lesions on the skin are somewhat similar to those found in the more usual type of blastomycosis—viz., verrucose patches with minute epidermal abscesses—but are generally of larger size, and visceral complications are the rule, the malady terminating almost always fatally. In the affected tissues peculiar large structures are seen, some of which may contain as many as 100 spore-like bodies (see p. 985).

4. *Gluteal Blastomycosis.*—This condition was described by Kartulis some years ago in Egypt. We have often observed it in Ceylon. The skin of the gluteal region—one nate or both nates—presents a diffuse induration, and is cribrated with the opening of sinuses, from which a thin pus exudes. The sinuses may be very deep and connected with each other, but in our cases did not communicate with the intestine. The pus does not contain grains, as is the case with actinomycosis. The patient may complain of pain and discomfort on sitting down. The disease is chronic.

---

[1] **Maxwell has reported from Formosa cases of a fistulous disease of the buttocks, which may be of the same nature. He is inclined, however, to consider them to be of amoebic origin.**

Diagnosis.—This is based, in the usual type of the malady, on the presence of verrucose patches with micro-abscesses, in which the fungi are found. The disease has been often confused with tuberculosis verrucosa, with a syphilide, with an epitheliomatous lesion, and, in the tropics, with atypical framboesia and even ringworm. The microscopical examination and cultivation of scrapings, or, better, of the pus of the miliary abscesses present in the lesions, will be necessary to clear the diagnosis. A droplet of the pus, or a minute portion of teased tissue, is placed on a slide with a drop of a 30 per cent. solution of potassium hydrate, and a cover-glass is placed on the preparation; after about half an hour in a temperate climate, and generally a few minutes only in a tropical climate, the tissue and pus cells are disintegrated by the potash solution, while the organisms, being resistant, can be easily seen. Cultures should also be made from the pus. It is important to note that yeast-like organisms may be frequently found as saprophytes on the surface of various ulcerated skin lesions, which have nothing to do with true blastomycosis.

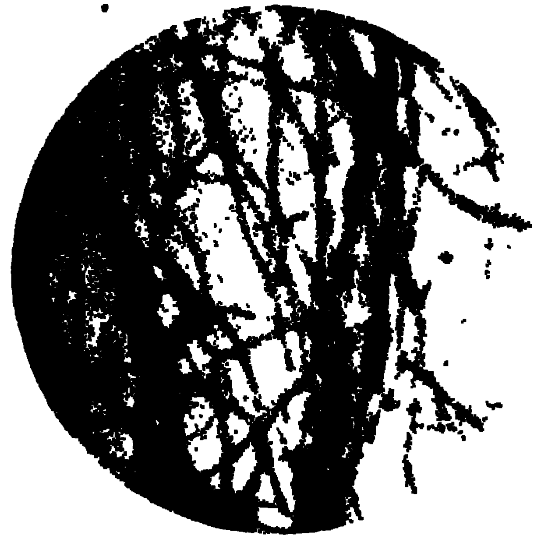

FIG. 834.—FUNGUS FOUND IN DERMATOSIS HYPHOMYCETICA INDICA. (BROTH CULTURE.)

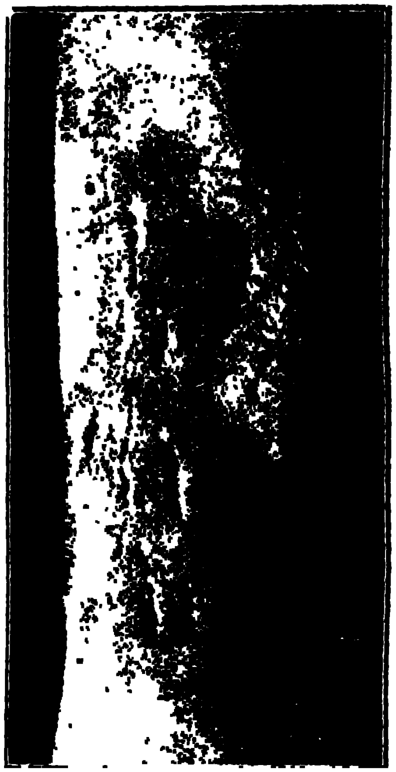

FIG. 835.—DERMATOSIS HYPHOMYCETICA INDICA (see p. 2086).

Oral blastomycosis may occasionally be confused with espundia, from which it is differentiated by the absence of Leishmania and presence of fungi. *Blastomycosis coccidioides* is easily diagnosed by the presence of bodies containing numerous—as many as 100—endospores. *Gluteal blastomycosis* is distinguished from actinomycotic and mycetomatous conditions by the absence of the grains and the characters of the fungi; from a syphilitic condition by the inefficacy of a mercurial treatment; from tubercular fistulous disease by the massive diffuse induration, and absence of tubercular cutireaction.

Prognosis.—The disease very rarely heals spontaneously. The general health in the common type of the malady is not much affected, but the patients complain of the disfigurement. Occasionally the organisms from the skin lesions enter the general circulation, and a condition similar to pyæmia develops. Cases of systemic blastomycosis terminating fatally, without any skin lesion, have also been described. The prognosis of blastomycosis coccidioides and oral blastomycosis is bad, while blastomycosis glutealis is most persistent, though the general health is not much affected.

Treatment.—Potassium iodide, given in large doses (gr. xv. to xx. three or four times daily), has a beneficial effect, though it is not so efficacious as in sporotrichosis. The application of Röntgen rays to the lesions is useful. In mild cases the local application of various disinfectants—*e.g.*, perchloride of mercury (1 in 1,000), diluted tincture of iodine, etc., may bring about a cure. The following ointment is useful, especially in the localization to the upper lip: Ichthyol, gr. xv; ung. belladonnæ, ʒii.; vaselini, ad ℥i. No treatment is apparently much use in blastomycosis coccidioides, in oropharyngeal blastomycosis, or in blastomycosis glutealis.

Dermatosis Hyphomycetica Indica.—This term has been used by Castellani to indicate a peculiar hyphomycetic condition he has once seen in Ceylon The patient had a number of gummatous swellings and indurated patches, but no warty lesions were present anywhere. A fungus was isolated which in various sugar broths and ordinary broth produced very long filaments, but owing to an accident could not be further studied

SPOROTRICHOSIS.

Schenk, in 1898, described a case of multiple chronic abscesses in the pus of which a *Sporotrichum* was found. Hektoen and Perkins reported two similar cases also in the United States in 1900. De Beurmann published in 1903 a case of similar nature in France. De Beurmann and Gougerot, from 1906 onwards, have published many cases, and have completely investigated the subject of human sporotrichosis bacteriologically and histologically, as well as clinically. Their researches have been confirmed by Gaucher and Monier-Vinard, Duval and Fago, Vaquez, Bonnot, Lambry, Adamson, Esmeni, and many others. Cases have been reported from the tropics by Lutz and Splendore in Brazil, and by us in Ceylon. Clair has observed the disease in Arab stokers on board some steamers of the Messageries Maritimes Company.

Ætiology.—The fungi causing the disease belong to the genus *Sporotrichum* Link, 1809, of which nine species have been so far described in man:—

Sporotrichum Link, 1809
S. ***schenki*** Hektoen and Perkins, 1901.
S. ***beurmanni*** Matruchot and Ramond, 1905.
S. ***dori*** de Beurmann and Gougerot, 1906.
S. ***gougeroti*** Matruchot, 1910.
S. ***jeanselmei*** Brumpt and Langeron, 1910.
S. ***indicum*** Castellani, 1908.
S. ***asteroides*** Splendore, 1909.
S. ***lesnei*** Vuillemin, 1910.
S. ***councilmani*** Wolbach, Sisson and Meier, 1917.

For the description of these organisms, see chapters on Fungi (p. 1117).

The species so far found in the tropics are—S. ***beurmanni*** Matruchot and Ramond in Brazil and Africa, S. ***asteroides*** Splendore, 1909, in Brazil, and S. ***indicum*** Castellani, 1908, in Ceylon. These fungi are morphologically very similar. In the human lesions the fungus appears morphologically as a yeast, and is very scarce. In cultures mycelial threads and numerous spores are seen. The spores are ovoid, 5 to 6 μ in length by 3 to 4 μ in breadth. The mycelial filaments are very slender (2 μ) in S. ***beurmanni*** and S. ***schenki***; somewhat broader ($2\frac{1}{2}$ to 3 μ) in S. ***indicum***. S. ***asteroides*** is characterized by the presence of peculiar radiate bodies in the affected tissues. These fungi grow easily on the ordinary culture media, best of all on Sabouraud's peptone-glucose agar. Colonies develop from the fourth to the tenth day as small white points, surrounded by a delicately rayed aureola of whitish colour. They gradually increase in size, coalesce, become convoluted, and take a dark greyish, brownish, and even black colour. These fungi, according to De Beurmann, may perhaps live saprophytic on vegetables (lettuce-leaves, and other kinds of vegetables used as salads) and on insects (flies, caterpillars, larvæ). According to De Beurmann, infection takes place by contact with unclean vegetables.

FIG. 836. SPOROTRICHIC LYMPHANGITIS.
(From a photograph by Splendore.)

The fungi may also, apparently, live saprophytically in the oral cavity and pharynx of certain individuals, who then become carriers.

The rat, mouse, monkey, cat, and very young guinea-pigs, are all more or less susceptible, and may be infected by subcutaneous or intraperitoneal inoculation. The rat is the most susceptible animal. In it Lutz and Splendore have described a spontaneous sporotrichosis due to a *Sporotrichum* apparently identical with *S. beurmanni*. Moore and Davis have described a case following the bite of a field-mouse. The patient's blood agglutinated equally well *S. schenki* and *S. beurmanni*. The affection has also been observed to occur spontaneously in the dog (Gougerot and Caravan) and in the mule (Fontoynont and Carougeau) in Madagascar.

Histopathology.—The histopathology of the cases due to *S. beurmanni* has been investigated by De Beurmann and Gougerot; that of the cases due to *S. asteroides* by Splendore; that of the cases due to *S. indicum* by ourselves. Whatever the causative species of *Sporotrichum*, the histological lesions are apparently the same, and correspond to the three principal types described by De Beurmann and Gougerot—viz., (1) An epithelioid type, with presence of giant cells—this corresponds to the tuberculoid type of De Beurmann and Gougerot; (2) a lympho-connective tissue or syphiloid reaction; (3) a polymorphonuclear or ecthymatiform type.

Symptomatology.—In a well-marked case, several gummatous-like swellings, situated in the subcutaneous tissue, are present on various parts of the body—the arms, legs, and trunk. The size varies from that of a small pea to that of an orange. On palpation, they are hard, resistant at first; later they soften, the skin becomes reddish or violaceous and after a time perforates. From the fistulous opening a yellowish homogeneous pus is slowly evacuated, or at times a thin serous discharge. In some cases the suppuration ceases, granulation sets in, and a coarse cheloid-like scar remains. In other cases the fistulous opening enlarges and a crateriform ulcer, with often a fungating fundus, develops. The lymphatic glands may occasionally become affected. The course of the disease is very chronic. In some cases deep gummata develop under the periosteum of various bones, and in the muscles. Large granulating ulcerations may form in the buccopharynx and larynx The general health, as a rule, is not much affected.

Clinical Varieties.—The commonest varieties met with are:—

1. The localized type, with sporotrichic chancre and ascending sporotrichic lymphangitis.
2. The disseminated gummatous type.
3. The disseminated ulcerative type, presenting often polymorphic lesions—viz., syphilitic-like, tubercular-like, ecthymatous, rupial, furuncular.
4. The extracutaneous type, with sporotrichic lesions of the mucous membranes, the muscles, the articulations, the bones, the organs of special sense, the internal organs—lungs, kidneys, etc.

De Beurmann has put on record a case of mycetoma of sporotrichic origin. Cases of systemic sporotrichosis have been described.

Diagnosis.—The principal clinical signs on which to base a *probable* diagnosis of sporotrichosis are the presence of gumma-like lesions while the patient is in a good general state of health; the mixture of lesions of different appearance: partial cup-shaped softening of the nodes, breaking down in the centre and ending in ulceration, with violaceous edges generally undermined; presence of viscous pus or of a serous lemon-yellow discharge; indolent evolution; absence in most cases of enlarged glands. The definite diagnosis can only be made by bacteriological methods. The simple microscopical examination of the pus of the abscesses, or scrapings of the ulcers, is not sufficient, as the fungus is extremely scarce. Cultivation must be resorted to. A few glucose-agar tubes are inoculated, and kept at room-temperature without capping. After four to ten days the first colonies of *Sporotrichum* will appear.

Treatment.—Potassium or sodium iodides in full doses (15 to 20 grains three to four times daily), well diluted in water or milk, induce a rapid disappearance of all the lesions. In persons who cannot take potassium iodide, saiodin in the same dose may be given in cachets. The ulcerated lesions may be dressed with a lotion of potass. iodide 10 parts, iodine 1 part, water 500 parts. Surgical measures should be avoided.

Pinoy has noted that the action of the iodides is increased by a salt-free diet.

Prophylaxis.—Any small wound should be disinfected with tr. iodi.

ACLADIOSIS.

Definition.—An ulcerative dermatomycosis caused by *Acladium castellanii* Pinoy.

Historical and Geographical Distribution.—The condition has been observed by Castellani since 1907 in Ceylon, but he did not fully describe it until 1916. Cases have been observed in Ceylon, the Federated Malay States, and Macedonia.

Ætiology.—The condition is caused by a fungus which Castellani isolated in Ceylon. Cultures were sent to Professor Pinoy, of the Pasteur Institute, who investigated it botanically and classified it, giving it the name of *Acladium castellanii* Pinoy, 1916. Professor Pinoy's description may be quoted:—

'The growth on artificial media (such as carrot, potato, glucose agar) consists of many small roundish masses, which later on may coalesce, covered by spiculated formations, giving them a prickly appearance, and consisting of erect, straight filaments, parallel to each other, or at times interlacing. These filaments are approximately 2 microns in diameter, and carry laterally pseudo-conidia of variable shape, cylindriform, pyriform, or spherical, attenuated in size at their points of insertion. Most of these pseudoconidia are 4 microns in length, with a breadth of 3 microns. This type of fructification recalls the type Acladium described by Bodin in certain species of the genus *Trichophyton* (Malmsten, 1848).

'These pseudoconidia become detached and then develop by sprouting, and mycelial filaments are formed. Certain filaments produce spherical chlamydospores arranged in small strings, as found in certain fungi of the genus Fusarium. These small chains of chlamydospores are very frequently terminal, the dimensions being variable—8-10 microns' (Fig. 595, p. 1113).

In cultures on carrot and potato the colonies are white, on glucose agar often amber colour. Very old cultures may show a certain amount of pigmentation (see p. 1112).

Histopathology.—The histopathological investigation of the condition is far from completed. From the preliminary investigation it would seem that the lesions are very similar to those one sees in sporotrichosis and that three types of lesions may be distinguished: (1) An epithelioid or tuberculoid type, with presence of giant cells; (2) a lympho-connective tissue type (syphiloid); (3) polymorphonuclear type (ecthymatous).

Clinical Symptoms.—In a well-marked case ulcerative lesions are present all over the body, though they are in smaller number or absent altogether on the face, scalp, palms, and soles. Most of the ulcers are sharply defined, roundish or oval, with red granulating fundus. Their appearance is well shown in the illustration, a photograph of a Ceylon case. In many cases there is abundant purulent secretion, which collects and dries up in thick yellow crusts, covering the ulcers. Gummata-like nodules and furuncle-like lesions may be observed. The superficial lymphatic glands may be enlarged. The lesions in most cases give very little pain, or none at all; itching is often completely absent, but occasionally the patient complains of slight pruritus. The general condition of the patient is not seriously affected for a long time, but he often complains of a certain degree of weakness and discomfort. Not infrequently there is serotine fever. The blood has been examined in two cases in the tropics; in one case in the Balcanic Zone: Wassermann reaction negative. In the first two cases red blood-corpuscles and hæmoglobin were slightly below the normal; in one there was eosinophilia (5 per cent.), which may have been due to a concomitant *Ascaris lumbricoides* infection. In the Macedonian case, the blood of which was examined, there was a distinct leucocytosis (16,000 leucocytes)

FIGS. 837 AND 838.—ACLADIUM CASTELLANII PINOY: HANGING-DROP CULTURE.

(*a*) After twenty-four hours', (*b*) after three days' growth.

of the polymorphonuclear type; in this patient there was abundant purulent secretion and serotine fever, which on some days reached 102° and 103° F.

Diagnosis.—A positive diagnosis can be made with certainty only by cultural methods. The microscopical examination alone is of very little use, hyphomycetic elements being as a rule absent microscopically in the scrapings from the ulcers and contents of nodules. The material should be inoculated in glucose agar tubes. Four to eight days after inoculation small, yellowish, amber-coloured colonies appear; they enlarge fairly rapidly, become hemispheric, and often coalesce in a knotty mass. At times the colonies may not fuse together; each colony then remains separate, reaches a large size, and occasionally presents peculiar radiating furrows as seen in certain species of trichophytons In many cases where the material has been collected from ulcerated lesions, the fungus grows in symbiosis with a coccus, and it may be difficult to separate the two organisms.

FIG. 839.—ACLADIOSIS OF THE ARM.

The malady is often taken for a syphilitic condition. The history, the negative examination of the lesions for spirochætes, the failure of mercury and salvarsan treatment, will exclude it. When the lesions are covered by raised, thick, bright, yellow crusts the condition must be differentiated from yaws: in acladiosis, on removing the crusts, ulcers are found, while in yaws, the typical frambœsiform nodules will be seen; in scrapings from yaws lesions the treponema will be found. Acladiosis can be differentiated from sporotrichosis and other affections of hyphomycetic origin by cultural methods.

Prognosis.—The course of the disease may be very long, and there is very little or no tendency to spontaneous cure; but if a proper treatment is carried out a cure can be obtained fairly rapidly in the majority of cases. A few cases respond to treatment extremely slowly.

Treatment.—Potassium iodide given in full doses (20 gr *ter diem*) acts satisfactorily. The drug appears to act at times more rapidly if given according to Professor Pinoy's method—viz., in conjunction with a salt-free diet. If potassium or sodium iodide is not well borne, sajodin and other similar preparations may be tried, but the result is not so satisfactory. Mercury and arsenic have no effect on the course of the malady. As regards local treatment, it is sufficient to keep the ulcers clean by using a weak mercury perchloride lotion.

CRYPTOCOCCOSIS EPIDERMICA.

Synonym.—Saccharomycosis epidermica (Castellani).

Historical and Geographical.—This condition was first described by Castellani in Ceylon. We have recently found cases in the Sudan and in the Balcanic Zone.

Ætiology.—The causal organism is *Cryptococcus epidermidis* Castellani, 1914.

Symptomatology.—The condition is fairly frequent in Europeans who have resided for some years in the tropics, but is also found in natives. It is characterized by the presence on the arms, and more rarely on the chest and neck, of small roundish patches of a dirty yellow or brownish colour, which can generally be removed by thorough scraping. These patches consist of large numbers of blastomyces-like elements of various size, rounded or oval, which so far have not been cultivated.

Treatment.—Thorough scraping with sand-soap and hot water is generally sufficient to remove the patches. In obstinate cases a salicylic sulphur ointment is useful.

INTERTRIGO SACCHAROMYCETICA.

Synonym.—Intertrigo Blastomycetica.

Remarks.—Cases of this affection have been observed by Castellani in Ceylon, and similar ones have later been reported by Whitfield and others in Europe. The affection is apparently rare. It generally attacks the scroto-crural and axillary regions. The affected skin is red, and there may be slight exudation. The borders of the eruption are fairly well marked, but never elevated. In most cases there is not much itching, and the affection may recover spontaneously.

Ætiology.—In scrapings a *Saccharomyces* (*S. samboni* Castellani, 1907), which is easily cultivated on sugar media, is found, or in other cases fungi of the genus *Monilia*.

Treatment.—The treatment consists in washing the affected parts with potassium permanganate lotion, 1 in 4,000, or resorcin, 1 in 100; followed by the application of powders of boric acid ʒi., talci ℥i.; or salicylic acid gr. x., talci ℥i.

ASPERGILLOSIS AND PENICILLIOSIS OF HAIRY PARTS.

The affected hairs—generally those of the beard and moustache, occasionally of the axilla—present dirty greyish or whitish punctiform formations, which on microscopical examination are seen to consist of penicillar or aspergillar fungi (*Penicillium barbæ*, *Asper-*

gillus barbæ). Occasionally both types of fungi are found on the same patient. The affection is very chronic. The diagnosis is easy, the characteristic aspergillus and penicillium fructifications distinguishing this condition from other parasitic nodular affections. The simplest method of treatment is by shaving, and afterwards using regularly a medicated soap, such as carbolic soap, tar soap, or sulphur soap. If the patient does not wish to shave his beard, turpentine may be tried.

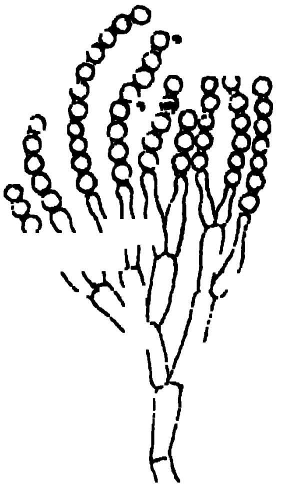

FIG. 840.—PENICILLIUM FRUCTIFICATION.

In natives who do not bathe frequently, such as old persons and beggars, the skin presents often large dark patches due to accumulated dirt, in which aspergillar and penicillar fungi are often present, living saprophytically. This condition has nothing to do with pinta, as a thorough scrubbing with soap will remove the dirt and the aspergillar and penicillar fungi which may be present.

PINTA.

Synonyms.—Mal de los Pintos, Mal del Pinto, Caraate, Tina, Quirica, Pannus Carateus (Alibert), Tache Endémique des Cordillières (Alibert), Lota, Cativi, Bulpiss (Lerch).

Definition.—The term ‘pinta’ does not indicate a single disease, but a group of closely allied dermatomycoses characterized by the presence of patches of various colour, due to different species of fungi of the genera *Aspergillus*, *Penicillium*, *Monilia*, and *Montoyella*.

History.—The disease first began to draw the attention of medical writers in the eighteenth century, though it was apparently well known to the inhabitants of the affected regions since remote times, as it is found to have formed the subject of prayers and supplications used by the Aztecs centuries before the Spanish Conquest.

A short description of the malady is found in the Encyclopædia of Polanko, of Mexico, in 1760; and in Juan de Velasco's ‘Historia,’ in 1789, in Columbia. Velasco believed the malady to have been imported by African slaves. A fairly complete description is given by Alibert, in 1829, under the name of ‘tache endémique des Cordillières,’ or ‘pannus carateus.’ Among the modern authors, the clinical and pathological investigation of Gomez, Uribe, Vribechyel, Iryz, Ruiz y Sandoval, Gastambido, may be mentioned.

More recently the investigation into the ætiology of pinta by Montoya has been of the greatest importance.

Climatology.—Pinta is practically limited to tropical America, where it is found in Venezuela, Peru, Chili, Central American States, Mexico. Cases have been reported from Brazil. It is extremely common in Columbia, where, according to Montoya, 4 per cent. of the total population is affected. There the patient affected with the disease is called ‘caratejo.’ The disease is not equally distributed; in each country there are localities where the disease is common, while other districts are almost unaffected. In Columbia it is the northern province of Santander which is more particularly affected; in Mexico the disease is most frequently found in the provinces of Tabaxo, Chiaspas, Valladolid, Michoacan.

A few cases of pinta have been reported from Egypt by Madden, Goodman, and Sandwith, and previously Legrain described somewhat similar cases from Tripoli and the Sahara. Legrain, however, did not find any fungus. A few isolated cases have also been reported from the Gold Coast, and others from the Philippine Islands by P. G. Woolley. In Ceylon and India only imported cases are seen.

Ætiology.—Previously to Ruiz y Sandoval and Montoya's investigations the disease used to be ascribed to many different causes. Some authors believed it to be due to the mineral salts (sulphates) contained in the waters of the mines and other localities where the malady is endemic; others considered it to be due simply to insanitary conditions, insufficient food, and a hot and damp climate; others, again, believed the affection to be induced by the action on the skin of volcanic cinders: while, according to some authorities, the malady was an hereditary complaint.

Ruiz y Sandoval, in Mexico, first detected the parasitic nature of pinta. He believed there was only one species of fungus to be found in the affection, and that the different colours of the patches were due to the different depths at which the fungus was growing in the various strata of the epidermis. Montoya's classical researches in 1898 clearly showed the plurality of species and genera of the fungi found in the disease, and demonstrated that each variety of pinta is due to a different fungus. More than twenty different species were found by him.

In the present state of our knowledge of pinta it is impossible to give a satisfactory classification of these fungi. The principal ones may be collected into the following groups:—

I. Fungi of genus *Aspergillus*: *Aspergillus pictor* Blanchard, 1895, and several other species. *A. pictor* is found in the pure violet variety of pinta; the other species are observed in the pure blue and bluish and violet-black varieties, as well as in a form of the red variety. Several of these species are not in reality true *Aspergilli*, as they possess organs of fructification intermediate between those of the genus *Aspergillus* and those of the genus *Penicillium*.

II. Fungi of genus *Penicillium*: *Penicillium montoyai* Castellani, 1907, and several other species. They are found in some greyish-violet varieties of pinta.

III. Fungi of genus *Monilia*: *Monilia montoyai* Castellani, 1907. Found in some cases of white pinta.

IV. Fungi of genus *Montoyella*: *Montoyella nigra* Castellani, 1907. Found in one variety of black pinta. *M. boxini* Castellani, 1907. Found in a red variety of pinta.

The term *Aspergillus* (*Trichophyton*) *pictor*, introduced by Blanchard in 1895, when the plurality of species of the fungi found in pinta had not yet been demonstrated, is now used in a restricted sense to indicate the *Aspergillus* found in the pure variety of the disease.

Montoya believes that the fungi found in Columbian pinta, or caraate, are different species from those found in Mexican pinta.

Appearance of the Fungi in Fresh Preparations.—Scrapings from the patches examined in liquor potassæ show in most cases between the epithelial cells long dichotomous mycelial threads, from which shorter and thicker branches take origin at various points. These thicker branches terminate in comparatively large fructifications. The morphological characters of these fructifications vary according to the species and genus of the fungus present. They may be typical aspergillar or penicillium-like fructifications, or they may show intermediate characters between those of *Aspergillus* and *Penicillium*. In many cases the fructification organ is represented by a pear-shaped or triangular formation, surmounted by five to six rods (sterigmata), each of which supports a string of five to six spores. The number of these spores, however, may vary. They are globular, have a smooth surface, show a double-contour, and their diameter is much larger than that of the mycelial tubes.

In the cases where the fungus present is a *Monilia* or a *Montoyella*, such or similar fructifications are absent, and only mycelial tubes and some scattered spores are seen.

Cultures.—The various fungi found in pinta are easily cultivated, the best medium being Sabouraud's maltose agar. The *optimum* temperature is between 30° and 40° C.

The composition of Sabouraud's medium

Maltose	4 grammes.
Peptone (Chassaing) ..	1 gramme.
Agar	1·5 grammes
Distilled water	100 c.c.

Culturally, the fungi may be divided in five groups

1. Those showing in cultures aspergillar fructifications.
2. Those showing penicillium fructifications.
3. Those showing intermediate fructifications between the *Aspergillus* and the *Penicillium*.
4. Those showing simpler fructifications characteristic of the genus *Monilia*—viz., a mycelial thread terminating in a single string or small bunch of roundish spores.
5. Those in which higher organs of reproduction are absent, and reproduction takes place somewhat similarly to what is observed in the genera *Microsporum* and *Trichophyton*—by conidia and terminal segmented and unsegmented 'spindles.' The fungi of this group, found by Montoya in a variety of black pinta, by Bodin, and later by Castellani, in a variety of red pinta, constitute the genus *Montoyella*.

Inoculation Experiments.—Montoya has tried to infect rabbits, using various cultures of the fungi found in the disease. On several occasions a desquamation of skin and loss of hair was observed, and some chromatic patches appeared. Uribe succeeded in inoculating several mulattoes.

According to Montoya, the fungi of pinta live saprophytically in certain waters, especially in those of mines and localities where the temperature is constantly high. He states that he obtained pure cultures of the pinta fungi direct from such waters. He has also found the same fungi as ectoparasites on the bodies of mosquitoes of the genus *Culex*, on sandflies (*Simulium*), and on the body of some bugs (*Clinocoris*), which are very common in the mines. He believes, therefore, that mosquitoes and other insects play a rôle in the transmission of the disease.

In some old chronic cases of pinta an *Acarus*—somewhat resembling *Acarus scabiei*, though larger—has been found to live in the epidermal squamæ, and some writers believe that this *Acarus* also plays a part in the transmission of the malady.

Predisposing Causes.—What the older authors believed to be the true causes of pinta—viz., a hot, damp, climate; insanitary surroundings and poor feeding; the mineral salts contained in the waters—are only predisposing causes, some of which, however, are of great importance. The hot, damp climate favours the growth of the fungi: the water of the mines, which contains a large amount of mineral salts (especially sulphates), produces after a time in those who use it for washing, etc., a dermatitis with fissures and other eczematous-like lesions which greatly facilitate the infection.

All races are liable to be attacked by the disease, but mulattoes seem to be particularly prone to become infected. Albinos are said to be immune. Both sexes are equally liable to become infected, though males, on account of their occupations, are more frequently affected. The malady generally appears between the age of fifteen and twenty-five, but it may appear at any age, and has been seen in children three or four years old.

It has been observed that individuals of the negro race are more liable to contract the black variety than any other kind of the disease, while whites are especially liable to contract the red variety. Miners and agricultural labourers are affected in most cases by the violet variety.

Symptomatology.—The disease begins very gradually. After an incubation period varying, according to different authors, between a few weeks and some months, one or several small slightly pruriginous spots appear on uncovered parts of the body. The spots increase very slowly in size, and some may fuse together. They are roundish, or may have an irregular outline. At first they are hardly raised above the normal skin. The surface of the patches is generally dry and rough, and is covered with fine pityriasic squamæ in recent cases, with larger and thicker scales in older ones. Occasionally, in chronic cases, the surface of the patches, instead of being dry, may be moist or somewhat greasy or glutinous.

The hairs of the affected regions become atrophied, and later on fall out. The shedding of hair is not due to the fungi invading directly the hair; it is due to a peculiar fibrosis of the hair follicle, at the place of the hair a hard formation remaining, like a grain of sand (fibroid folliculitis of Montoya).

Pruritus is generally well marked, especially at night-time. There are often patches of hyperkeratosis on the palms and soles, and the normal lines and sulci appear much deeper.

Old chronic cases occasionally exhale a peculiar musty odour, which has been compared to the smell of cat's urine, or to the bad smell of dirty linen kept in a warm, damp place.

The affection may spread to the whole body, except the palms of the hands and the soles of the feet. The nails are never attacked. The scalp is not usually affected.

The disease has no tendency to spontaneous cure. Its course is very chronic, and may last the whole of the patient's life.

Some of the older authors state that the patients during the incubation period suffer from fever, vomiting, and diarrhœa. Montoya says that pinta patients have not got an odour *sui generis*, as stated by most observers. In cleanly patients no smell whatever is noticeable, apart from the peculiar odour of the negro race.

Clinical Varieties.—Clinically, six different varieties may be distinguished, each of which shows several subvarieties:—

1. The Black Variety.
he Blue Variety.
he Violet Variety.
he Red Variety.
he Yellow Variety.
he White Variety.

Black Variety.—The patches are of a black colour, and are very often found on the face, though they may be present on any other part of the body except the palms and soles, similarly to all the other varieties. The patches are hardly raised, and their surface is slightly desquamating. Pruritus is generally complained of, but is not, as a rule, so unbearable as in the other varieties. Black pinta is found in negroes more frequently than in individuals of Caucasian race. The course is very chronic. The treatment is difficult, though not so difficult as in the other varieties.

Black pinta shows two subvarieties—one is characterized by the presence of patches of a black-violet colour: the other by patches of jet-black, indian-ink black colour. The fungus found in the first is an *Aspergillus* (species undetermined): in the second a ***Montoyella*** (***M. nigra***).

Blue Variety.—This is much less frequent than black pinta. The patches are of a blue colour. They generally begin to appear first on the dorsum of the hands, and then tend to spread over the whole body—uncovered as well as covered parts. There generally is intense pruritus.

The fungus usually found in blue pinta is ***Aspergillus.***

Violet Variety.—Apart from the colour of the patches, which is violet, the clinical symptoms and course of this variety are identical with those of blue pinta. It is extremely common among rural labourers and miners.

There are numerous subvarieties of violet pinta. In some cases the patches are of a pure violet colour; in other cases the colour may be violet-greyish, violet-brownish, violet-purplish. There are cases in which the patches are at first of a greenish colour, to become violet-bluish later on. The fungus found in the pure violet pinta is an *Aspergillus* (*A. pictor* Blanchard, 1895); the fungus found in the violet-greyish cases is a *Penicillium*—*P. montoyai* Castellani, 1907; the fungi found in the other varieties are *Aspergilli* or fungi presenting transition characters between the *Aspergillus* and the *Penicillium*.

Red Variety.—This is the commonest variety found in white patients. The patches first develop, as a rule, on the dorsum of the hands and feet, and spread to large portions of the body. The patches are red—often brick-red—and usually show a rather abundant desquamation. Pruritus is very distressing, especially at night-time. Secondary lesions due to scratchings and inoculation of pyogenic micro-organisms are not rare. Ulcerative lesions have been reported by several observers as occasionally occurring.

In some cases of red pinta an *Aspergillus* (species not determined) is found; in others a fungus of the genus *Montoyella*—*M. bodini* Castellani, 1907, found by Bodin in 1903 in a patient who was under the treatment of Darier.

Castellani, in 1907, found the same or a very similar *Montoyella* in a case of red pinta observed in a European sailor who had long been in tropical America. In this case the disease had not yet spread much. Besides the red patches, there was on the right forearm a small greyish-violet spot, in which a fungus was found, which gave *Penicillium* fructifications in cultures (*P. montoyai*).

Red pinta is more serious than any other variety, as it affects not only the superficial strata of the epidermis, but the rete Malpighii as well as the corium.

Yellow Variety.—Very common among half-castes. It generally begins on the chest or arms. The patches are yellow, and at first are not pruriginous and not desquamating. In old cases, however, there is pruritus. This variety is very frequently mixed with patches of white pinta, and is difficult to cure. The fungi found belong to the genera *Monilia* and *Aspergillus*.

White Variety.—The patches are of a dull white colour, and are generally very large. The surface is usually rough and desquamating, but at times it may be smooth. In some cases a fungus of the genus *Monilia* is present, but, according to Montoya, in other cases no fungus whatever is to be found. Montoya considers the white variety of pinta to represent in many cases the ultimate retrogressive stage of all the other varieties except the red. The patches of white pinta would be in such cases in reality unpigmented leucoderma-like areas due to the disturbing action of the various fungi on the pigmentation processes of the skin.

Montoya's belief on the nature of white pinta in some cases is supported by Castellani's observations on tinea flava and tinea alba. In both these dermatomycoses white, pseudo-leucodermic patches may occasionally be seen long after the fungus has died out, and these patches may remain unpigmented for months and years.

Mixed Variety.—Not infrequently the same patient may be affected with several varieties of pinta, presenting a grotesque tattooed or piebald appearance.

It is especially white pinta which is found associated with one or more of the other varieties.

Diagnosis.—This does not present any difficulty in the countries where the disease is endemic. In any doubtful case the microscopical examination, supplemented when necessary by the use of cultural methods, will clear the diagnosis.

Differential Diagnosis—*Tinea nigra.* In contrast to the black variety of pinta, tinea nigra is very superficial, does not extend to large portions of the body, may attack the palms of the hands, is not pruriginous, is easily cured except when affecting the palms. The microscopical examination of scrapings from patches of tinea nigra will show mycelial tubes of irregular shape and large globular spores collected in bunches. The spores are grouped together in a somewhat similar manner to what one sees in pityriasis versicolor.

Tinea Flava.—In contrast to yellow pinta, the fungus of tinea flava is a *Malassezia*, has the same morphological characters of the fungus found in pityriasis versicolor, and cannot be grown artificially.

Tinea Albigena and Tinea Alba.—These are generalized trichophytic and epidermophytic affections, and are easily distinguished by the characters of the fungi.

Leprosy can be distinguished from white pinta lesions by the sensibility not being impaired in pinta.

Only white pinta patches with no fungus might be mistaken for *leucoderma* on superficial examination. White pinta is very often associated with other varieties of pinta, which are easily diagnosed. Leucodermic patches are smooth, non-pruriginous, and the skin surrounding them is often hyperpigmented.

Prognosis.—Pinta, though not a fatal disease, must be considered a serious affection, as its course is chronic and the treatment very difficult. In most cases the general health remains satisfactory, but the disfigurement is very distressing to the patients, who often become nervous and irritable. The pruritus, which is generally more marked at night, is also a cause of great distress and sleeplessness.

Treatment.—The popular treatment in Columbia is citrine ointment (mercury nitrate ointment). Other parasiticides have been tried, with a varying degree of success. When the eruption is at the very beginning, tincture of iodine may suffice. The best results have been obtained by using chrysarobin (chrysarobin, gr. x. to xxx.; ung. zinci ox., ℥i.). This must be applied cautiously. When the malady affects large tracts of the body, only a portion should be treated at a time, to prevent as far as possible symptoms of absorption. The urine should be regularly analyzed during the treatment. The chrysarobin ointment must not be applied to the face, lest a severe conjunctivitis should develop. For the face a resorcin, or resorcin-sulphur, or resorcin-salicylic, or salicylic acid ointment (resorcini, gr. xxx. to ʒi.; ac. salicylici, gr. xv.; vaseline, ℥i.), is advisable, or citrine ointment may be used.

Montoya recommends chrysarobin dissolved in chloroform (chrysarobin 10 parts, chloroform 90 parts). Apply with a fine brush. When dry, apply gutta-percha dissolved in chloroform (gutta percha 10 parts, chloroform 90 parts).

Chrysarobin may conveniently be applied in the form of a vernisol varnish cent.).

PIEDRA.

Synonym.—Trichosporosis Tropica.

Definition.—Piedra is a mycotic disease of some parts of South America causing very hard, small nodosities on the hair.

Historical and Geographical. The condition has been known locally in Columbia since remote times, but the first scientific descriptions are due to Desenne (1878), Morris (1879), Osario, and Megalhães. More recently the condition has been studied by Juhel Renoy, Pernet, J. M. H. MacLeod, Horta, and others. This disease of the hair is common in some districts of Columbia, especially the valley of Canca; but closely allied conditions are observed in several parts of the tropics, and occasionally in temperate zones (*piedra nostras*).

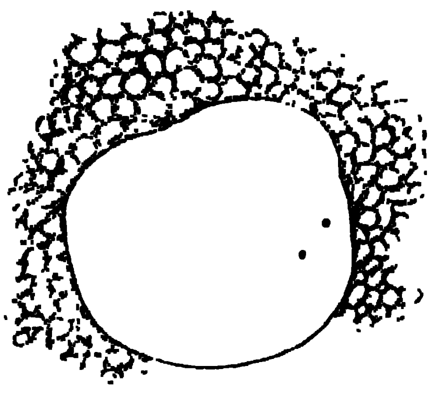

Fig. 841.—Transverse Section through a Piedra Nodule

Fig. 842.—Piedra.

Ætiology.—If an affected hair is washed in ether, and then treated with liquor potassae, and examined microscopically, the nodules will be seen to consist of large polyhedric refringent bodies, held together by an amorphous substance acting as cement. These bodies are the spores of the fungus causing the disease (*Trichosporum giganteum* Behrend, 1890). The description of the fungus is given on p. 1101. In Columbia it is generally believed that the infection takes place by washing the hair with a mucilaginous oil, much used by the women of the country. In British

Guiana natives consider it to be due to bathing in certain white or milky waters, while it does not occur if they bathe in the brown peat bush waters.

Symptomatology.—The hair of the head of women, and less frequently the hair of the head and beard of men, is affected. The affected hairs present strings of pin-head-sized nodosities, which are better felt than seen. The nodosities may be very numerous, and are found on the surface of the hair-shaft, either on one side or surrounding it like a sheath. They are black and hard, though not so hard as the name piedra (stone) would imply, and a kind of crepitation is produced when the hair is combed. There is often matting and knotting of the hair. The disease is chronic, and the nodosities do not disappear spontaneously.

Horta has described a variety of piedra in Brazil, characterized by the nodules containing large cyst-like structures, which Pinoy considers to be probably asci (see p. 1102).

Diagnosis.—The microscopical examination of the nodosities renders the diagnosis easy.

Prognosis.—The affection is of long duration, and has no tendency to spontaneous cure.

Treatment.—This is difficult. It has been recommended to apply a 5 per cent. salicylic alcoholic solution or benzene and turpentine to the hair, and to wash the head regularly with a perchloride lotion (1 in 2,000). In obstinate cases it is necessary to shave the head.

Trichosporosis Indica.

In India and Ceylon a condition similar to piedra is occasionally observed. It is, however, much less severe, a few minute nodules only being present on the hairs of the beard and moustache, and the hair of the scalp being rarely affected. The fungus seems to be different from that of the Columbian piedra.

Trichosporosis of Temperate Zones.

Cases of trichosporosis of temperate zones or piedra nostras (tinea nodosa) have been described by Biegel (1869), Caro, Behrend, Unna, Pick, Vuillemin. The nodosities in such cases have been found on the hairs of the moustache and beard, not on the hairs of the head. The fungi are slightly different from *Trichosporum giganteum*. Several species have been described—*Trichosporum beigeli* Rabenhorst, 1867, *T. ovoides* Behrend, 1890 *T. ovale* Unna 1896.

TRICHOMYCOSIS FLAVA, RUBRA, NIGRA.

Synonyms.—Trichomycosis axillaris, Trichonocardiasis, Tropical lepothrix, Castellani's Trichomycosis, Trichomycosis chromatica, Chromotrichomycosis.

Definition.—A nodular affection of the hair, usually of the axillary regions, caused by *Cohnistreptothrix tenuis* Castellani (*Nocardia tenuis* Castellani), either alone or in symbiosis with chromogenic cocci.

Historical.—Nodular affections of the hair have been described by European observers under various names, such as Lepothrix (E. Wilson), Trichomycosis nodosa (Patterson), Trichomycosis palmellina (Pick), but a great deal of confusion has existed until recently on the subject, very different clinical descriptions having been given and the condition being ascribed to widely different germs.

Paxton, Wilson, Pick, and later Payne, Patterson, Crocker, Pusey, etc., described the hairs as presenting irregularly lobed masses of hard consistency in which were often embedded some of the fibres of the cortex.

According to Crocker, the fibres of the whole shaft may be split up and the hair may break off with a brush like termination. The researches on the ætiology by various authorities gave the most widely different results, various bacilli being described by Payne and Patterson, a diplococcus by Eisner and later Sonnenberg, and a micrococcus by Colombini, etc. Babès, Pick, Balzer, and Barthemly considered that the *Bacillus prodigiosus* played a rôle in the causation of the affection

In 1911 Castellani carried out an investigation in the tropics, describing the condition as seen there and differentiating three varieties- the yellow variety, the black variety, the red variety. He demonstrated that the yellow variety was caused by a nocardia (*Nocardia* or *Cohnistreptothrix tenuis* Castellani); the black variety by the same nocardia plus a black pigment producing coccus (*Nigrococcus nigrescens* Castellani) living in symbiosis with it; the red variety by the same nocardia plus a red pigment producing coccus living in symbiosis with it, and which was later on called *Rhodococcus castellanii* by Chalmers and O'Farrell. Castellani's work was confirmed and amplified in the Sudan by Chalmers and O'Farrell, who suggested for the affection the term 'trichonocardiasis', in West Africa by Macfie, who described a variety of the red type: *fusca*; and by various observers in several other countries. In 1915-1918 Castellani observed in the Balcanic-Adriatic Zone the three varieties he had described in the tropics, and found the same organisms.

Ætiology.—The researches of Castellani have demonstrated that the yellow variety is due to a very thin, bacillary-like fungus, for which he proposed the name *Nocardia tenuis*, later changed into *Cohnistreptothrix tenuis*. The black and red varieties are due to a symbiosis of this fungus with chromogenic cocci, a coccus producing black pigment in the black variety, a coccus producing a red pigment in the red type.

Nocardia tenuis Castellani, 1912 (*Cohnistreptothrix tenuis* Castellani, 1912) — The microscopic examination of the nodules reveals the presence of enormous numbers of bacillary like bodies, which are Gram positive, but not acid-fast. If the nodules are kept in alcohol or formalin for several months, the fungus apparently loses partially or totally its property of being stainable by Gram's method. They vary in length, 4 to 10 μ and more; the average breadth is approximately 0·3 to 0·6 μ, they may be straight or variously bent, occasionally branching; they are fairly closely packed together, and are embedded in an amorphous cementing substance In regard to cultivation, Chalmers and O'Farrell observed some slight growth in hanging drops of equal parts of human serum and normal saline. Macfie in one case succeeded in cultivating the fungus on ascitic agar, the colonies being very small and translucent.

Characters of the Coccus-like Organism found in the Black Variety (*Micrococcus* or *Nigrococcus nigrescens* Castellani, 1911).—It is a Gram-positive, rather large, non-motile coccus, which in certain media may take the appearance of a cocco-bacillus. Sugar media are more suitable for the growth of the organism than the ordinary agar.

Sabouraud Agar.—Colonies appear twenty-four to forty-eight hours after inoculation. They are roundish, at first white, but after a couple of days the centre of each colony turns black, and this pigmentation slowly spreads excentrically. After a time the colonies coalesce into a jet-black mass.

Glucose.—Growth similar to Sabouraud, but slightly less abundant. The black pigmentation develops from the centre of the colonies and slowly spreads towards the periphery

Ordinary Laboratory Agar.—Growth much less abundant than on most sugar agars, and black pigmentation less marked.

Levulose Agar.—Identical to glucose.

Saccharine Agar.—The pigmentation is less pronounced, and does not spread to the whole of the growth.

Raffinose Agar.—Same as saccharine.

Lactose Agar.—Scanty pigmentation.

Alkaline Maltose Agar.—Black pigmentation well marked, though in many cases it does not extend to the whole of the growth.

Acid Maltose Agar.—Growth less abundant than on acid maltose. Black pigmentation well marked.

Mannite Agar.—As alkaline maltose.

Inulin Agar.—As alkaline maltose, but pigmentation less pronounced.

Saccharose.—As inulin.

Glycerine Agar.—Abundant growth, the whole of which after a time becomes of jet-black colour.

Galactose.—As inulin.

Adonite.—Like acid maltose.

Serum.—Growth fairly abundant, but there is only a trace of pigmentation. The medium is not liquefied.

Gelatine.—No liquefaction. The growth on the surface shows after a time some dark pigmentation, but the colonies along the stab are white.

Milk.—No change.

Broth.—General turbidity. A thin pellicle is often present. The microscopical examination shows cocci arranged in pairs or irregularly. They are not capsulated.

Peptone Water.—Some growth at the bottom, while the rest of the tube is clear.

Sugar Broths.—No formation of acid or gas

Indol.—Most strains produce a trace of indol.

Characters of the Coccus-like Organism found in the Red Variety of the Affection.—The coccus found in the red variety is more difficult to isolate and grow than the coccus observed in the black type of the affection. As a rule it grows better and shows more pigment on ordinary agar than on sugar media. It is non-motile and Gram-positive.

Agar.—The growth is at first white, then a red or red-yellowish or yellow spot appears in the centre. The pigmentation very slowly progresses towards the periphery, but seldom, if ever, spreads to the whole of the growth. On maltose and glucose agar the same pigmentation is present, but on most of the other sugar media no pigment is produced. Gelatine and serum are not liquefied. This coccus, as already stated, is Gram-positive and non-motile. The coccus has been recently further investigated by Chalmers and O'Farrell, who have observed that the best medium for showing the pigment is the potato They have called the coccus *Rhodococcus castellanii*.

Symptomatology.—The affected hairs of the axilla present nodular formations, plainly visible to the naked eye, of rather soft consistency. They are easily removed by scraping with a triangular needle or any similar instrument. The formations are either yellow or black, or, less frequently, red. They may be very abundant, and form a yellow, or black, or red sheath round the hair (Figs. 843 and 844), which may at times become lustreless and depigmented. The same patient may have two varieties: The hairs of one armpit may show the yellow variety, while the hairs of the other armpit may present the black type. Sometimes the same individual hair may present some of the nodules yellow and others black, or, rarely, red. We have not yet observed all the three varieties present at the same time on the same patient.

The microscopical examination with a low power shows that the affected hair is covered at several places by roundish formations, partially or totally encircling the shaft. Using a higher power, these formations will be seen to consist, in the yellow variety, of enormous numbers of bacillary-like bodies embedded into an amorphous cementing substance. In the red and black varieties in addition to these masses of bacillary bodies which are the mycelial segments of the *Nocardia* (*Cohnistreptothrix*), large groups of cocci-like bodies are observed. The affection in our cases was never associated with chromidrosis. It may attack the pubic hair.

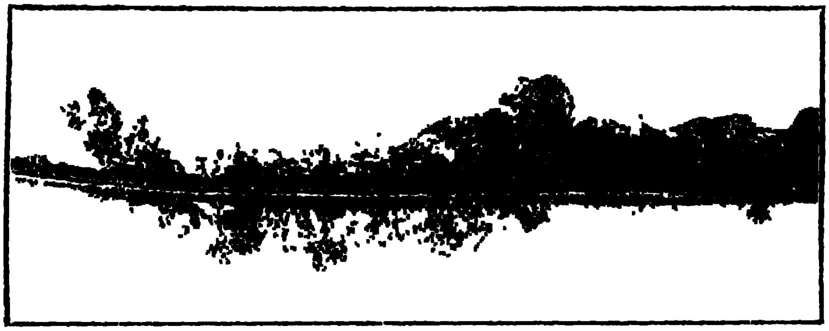

FIG. 843.—TRICHOMYCOSIS AXILLARIS FLAVA.

FIG. 844.—TRICHOMYCOSIS AXILLARIS NIGRA.

Macfie has described a subvariety of the red type, of less vivid colour: *fusca*. It is caused by *Cohnistreptothrix tenuis* plus a coccus which seems to be a variety of *M. castellanii*.

Diagnosis.—This is based on the presence of yellow, black, or red, rather soft, nodules on the hairs of the axillary regions, which, on microscopical and cultural examination, show presence of *Nocardia tenuis* (*Cohnistreptothrix tenuis*) alone, or with *Micrococcus* (*Nigrococcus*) *nigrescens* or *Micrococcus* (*Rhodococcus*) *castellanii*.

Differential Diagnosis.—The condition must be differentiated from the other nodular parasitic conditions of the hair, viz.:—

1. Trichosporosis tropica, or piedra.
2. Unna's trichosporosis, or piedra nostras.
3. Behrend's trichosporosis or 'nodular trichomycosis.'
4. Beigel's trichosporosis, or tinea nodosa.
5. Du Bois's trichosporosis.

1. Trichosporosis tropica, or piedra, generally affects the hair of the head. The nodules are extremely hard, hence the name 'piedra.' The fungus found belongs to the genus *Trichosporum* (*Trichosporum giganteum* Behrend, 1890).

2. Unna's trichosporosis, or piedra nostras, has been described by Unna in the hair of the moustache and beard. It is due to *Trichosporon ovale* (Unna, 1896).

3. Behrend's trichosporosis, or 'nodular trichomycosis,' described by Behrend, affecting the hair of the beard. It is due to *Trichosporum ovoides* (Behrend, 1890).

4. 'Beigel's trichosporosis,' or 'tinea nodosa,' discovered in London by Cheadle and Morris, and later in Breslau, Nancy, etc. It attacks the hairs of the head, and is due to *Trichosporum beigeli* (Rabenhorst, 1867).

5. Du Bois's trichosporosis of the hairs of the pubic region due to *Trichosporum glycophiles* (Du Bois, 1910).

Trichomycosis axillaris flava, rubra, and nigra has nothing to do with piedra or with any other form of trichosporosis, as no *Trichosporum* is found, the fungus being a *Nocardia* or more correctly a *Cohnistreptothrix*, with very thin, bacillary like mycelium. The types of the condition we have seen in Europe are very similar or identical with those we have seen in the tropics, except that in temperate zones we have never observed the black variety. The nodules were not very hard and the hairs not brittle, though European observers describe the European type as being characterized by the presence of hard nodules and the hairs becoming brittle.

Course and Prognosis.—The course is chronic, but the condition may subside or disappear on the patient going to a cold climate. The affection, if of very little pathological importance, has a certain practical interest, being much objected to by patients, especially by ladies.

Treatment.—The treatment originally used by Castellani is often efficacious. It consists in dabbing the hair two or three times daily with a solution of formalin in spirit (ʒi.-℥vi.) and applying at night a sulphur ointment (2 to 5 per cent.). Shaving, Tr. Iodi, and a salicylic alcoholic lotion, have been recommended.

RARER NODULAR AND GUMMATOUS AFFECTIONS OF HYPHOMYCETIC ORIGIN.

Hemisporosis.

Historical and Geographical.—Gougerot and Craven described a case of osteoperiostitis due to *Hemispora stellata* Vuillemin some years ago. Later Auvray and Bidot found the same fungus in a generalized nodular affection, and De Beurmann, Clair, and Gougerot found it in a gumma situated on the penis of a negro.

Ætiology.—The condition is due to a fungus, *Hemispora stellata* Vuillemin, the description of which is given on p. 1108.

Histopathology.—The histological lesions resemble those of tuberculosis cutis, as noted by Auvray and Bidot.

Symptomatology.—Gumma-like swellings are present, either single or multiple. These may later ulcerate. A chronic osteoperiostitis, with thickening of the tibia somewhat resembling the type due to syphilis, has been described. Mercury, however, had no effect.

Diagnosis.—This is based on isolating the fungus. The fungus microscopically is seldom if ever seen in the lesions, and cultures are necessary. These are carried out in the same manner as for sporotrichosis.

Treatment.—Potassium iodide given in full doses (gr. xv.-xx.) three times daily is very efficacious.

Acremoniosis.

There is only one case on record of this condition by Potron and Noisette in France. The condition is due to a fungus, *Acremonium potronii* Vuillemin, 1911, which has been described on p. 1121. The patient had fever, which was at first suspected to be typhoid, and several gumma-like swellings developed, which slowly ulcerated. They were not painful. The proximal glands were not enlarged.

Diagnosis.—This is based on finding the fungus by cultural methods.

Treatment.—In the only case known an intensive potassium iodide treatment cured the condition.

Enantiothamnosis.

Definition.—A nodular condition due to a fungus, *Enantiothamnus braulti* Pinoy, 1911.

Historical and Geographical.—This condition has been described by Brault in Northern Africa, who isolated the fungus, the complete botanical description of which we owe to Pinoy.

Ætiology.—The causative fungus is *E. braulti* Pinoy, 1911 (see p. 1096).

Symptomatology.—The condition in the only case so far known was characterized by the presence of nodules on the gluteal regions, the size of a pea to a small egg. The nodules had a central crateriform opening, from which some pus exuded.

Diagnosis.—This is based on cultivating the fungus from the lesions.

Treatment.—This is surgical, but first potassium iodide might be tried.

Cladosporiosis.

Definition.—A nodular condition due to *Cladosporium penicilloides* Gueguen, 1911.

Remarks.—There is another tropical condition due to a fungus of the genus *Cladosporium*—viz., tinea nigra—but this affection is clinically so different that we do not give it under the heading Cladosporiosis. We have given a separate description of it (see p. 1101).

Historical.—Fontoynont isolated the fungus from a case in Madagascar. Gueguen placed it in the genus *Cladosporium* and named it *C. penicilloides* Gueguen, 1911, and Verdun called it *C. madagascariense* Verdun, 1913 (*vide* pp. 1100 and 1101).

Symptomatology.—In the only case so far known, that of Fontoynont, gummatous nodules were present on the leg, some of which slowly ulcerated.

Treatment.—Potassium iodide has apparently very little efficacy in this condition.

Scopulariopsosis.

This condition is due to *Scopulariopsis blochi* Matruchot, 1911, and *S. koningii* Vuillemin, 1912. Two cases have been reported so far from France. The patients presented gummata and verrucose patches on the skin. Lymphangitis was noted in one case. The diagnosis is based on finding culturally the fungi. The treatment consists in giving large doses of iodides.

It is to be noted that Pinoy and other authorities doubt the pathogenic rôle attributed to *S. blochi*.

CHAPTER XCIII

MYCETOMA AND PARAMYCETOMA

General remarks--The mycetomas--The maduromycoses--The actinomycoses--The paramycetomas--The pseudomycetomas--Actinomycosis of the body--Nodular actinomycosis--Trench foot--References.

GENERAL REMARKS.

THE subject of the mycetomas has for years been in an exceedingly confused condition, because there has been no clear conception as to the exact meaning of the term, and no scheme whereby the fungi associated with the disease could be identified. Further, the curious relationship of the disease to malignant growths of various descriptions does not appear to have been realized until lately. The labours of Pinoy, of Brumpt, and those of Chalmers with Archibald and Christopherson, systematically continued for years, have enabled a certain amount of information to be gathered together in understandable form.

There are three distinct conditions which require to be studied - viz., the Mycetomas, the Paramycetomas, and the Pseudomycetomas--and detailed references to the fungi associated with these forms will be found in Chapter XXXIX. (p. 1035), which deals with the Fungi Imperfecti; in addition, a few remarks are necessary with regard to actinomycosis of the body.

THE MYCETOMAS.

Synonyms.--Madura foot, the Fungus disease of India, Godfrey and Eyre's Tubercular disease, Endemic degeneration of the bones of the foot, Morbus tuberculosis Pedis, Morbus Pedis Entophyticus, Podelkoma, La Maladie de Ballingall, Slipada, Hatty-ka-Pung, Keerenagrah (signifying a dwelling of worms), Kirudeo (signifying a dwelling of worms), Ghootloo Mahdee (signifying eggs of insects probably so called from the small bodies found in the discharge).

Nomenclature.– In 1846, Colebrook of Madura said that the disease was commonly known in some parts of Southern India as 'Madura foot.'

In 1860, Vandyke Carter applied the term 'mycetoma,' or fungus tumour (μύκης, a fungus, and οἴδημα, a tumour), to that variety of Madura foot which contained black granules, and one year later included under this name the white or yellow variety of the same complaint with which he had become acquainted.

Definition.—The term 'mycetoma' includes all growths and granulations which produce enlargement, deformity, or destruction in any portion of the tissues of man or animals, and which are caused by the invasion of the affected area by fungi belonging to different genera and species, which produce bodies of varying dimensions, colour, and shape, composed of hyphæ, and sometimes chlamydospores, embedded in a matrix. These bodies, which are capable of giving rise to mycelial filaments, on germination, are termed 'grains,' and are found either embedded in the pathological tissue forming these growths and granulations, or escaping freely in the discharge therefrom. In addition, eosinophile bodies can usually be seen.

Early History.—According to Waring, as quoted by Collas, the Sanscrit work 'Vaweda,' by which is probably meant, 'At'harvavéda,' describes a disease of the foot termed 'padavalmicum,' which causes swelling and the formation of little fleshy tumours, which, after an interval of a year from the commencement of the disease, discharge a peculiar fluid.

This disease is distinguished from another malady of the foot which is called 'slipatham,' or elephant foot.

If the above is a correct quotation from the 'At'harvavéda,' then the Ancient Indian surgeons must have distinguished elephantiasis of the foot from such conditions as might have been produced therein by mycetoma, yaws, etc.

It is, however, curious that, like Collas, we have been unable to find any account of such a disease in the writings of Suśruta.

The term 'perical,' used by Kaempfer in 1712, is applicable to any enlargement of the foot, whether caused by elephantiasis, mycetoma, or yaws, but the Pondichéry missionary of 1714 appears to have seen the disease mycetoma, and possibly the actinomycotic variety, because he describes under the term 'fourmilière des vers' an incurable disease of the foot in which numerous small ulcers form, which intercommunicate by means of canals full of worms. These canals are described as being peculiar in that if one closes another opens.

Heyne probably recognized some sort of a mycetoma, in 1806, in the foot of the Rajah's brother at Cuddapah, and Brett's 'adipose sarcoma,' described in 1840, may have been of the same nature.

Madura Foot Period.—With the closing years of the last period it will be noticed that it began to dawn upon the medical men of India that there existed in that country a peculiar disease of the foot, and this was emphasized by Gill of Madura, who, in 1842, described a condition of that member which was characterized by marked deformity and fungoid excrescences, from which flowed an offensive ichorous discharge, while internally the disease produced a condition resembling fibro-cartilage, and destroyed joints, cartilages, and ligaments.

Four years later, Colebrook, Gill's successor at the Madura Dispensary, confirmed these observations, and stated that the disease was commonly known in some parts of India as 'Madura foot.' As no mention is made, as far as we know, by these authors of any black pigment being present in their cases, we conclude that probably they saw the actinomycotic variety of mycetoma.

It is interesting to note that about this time (1845) von Langenbeck, in Kiel, made illustrations of some curious bodies which he considered to be fungal in nature, and which he found in the pus from a case of spinal caries. Unfortunately he never published this observation, which was made known by Israel one year after Bollinger's discovery, which will be mentioned below.

In 1848, Lebert found some peculiar spherical yellowish bodies, about the size of a pin's head, in some thick gelatinous pus which Louis had obtained from an abscess associated with much swelling of the thoracic wall in a man, aged fifty years, in Paris. These bodies were carefully examined, both microscopically and chemically, and drawings were made which were subsequently published by Lebert (1857).

We have examined copies of these drawings, and they represent in a typical manner the fungus of an actinomycosis. Lebert, however, failed to recognize their fungal nature.

In 1855, Smith, in London, made some drawings for Paget of a tumour of the upper jaw, in which an organism resembling a ray fungus is portrayed. These drawings were published by Kanthack (1896).

Also in 1855, Ballingall, in India, described a disease of the foot, in the discharge from which he found bodies composed of large cells with transparent fringes containing irregular spicules, or simply composed of radiating spicules without cells. In 1858, Rustomji described a variety of Madura foot in which he found small, soft, yellowish granules, and which he distinguished from another variety of the same disease, in which he found a dark, soft, thick substance. Rustomji's first variety we call *yellow actinomycosis* and his second variety *black maduromycosis.*

We will now consider the subject of the Maduromycoses.

THE MADUROMYCOSES.

Definition.—The Maduromycoses are those forms of mycetoma which possess grains composed of large segmented mycelial filaments, possessing well-defined walls and usually chlamydospores.

History.— Excluding some ancient references discovered by Collas, to which Corre has drawn attention, and which will be considered when we discuss that author's writings, the history of the black maduromycoses commences in 1845 in India, where Garrison-Surgeon Godfrey, in his Departmental Report of the Public Dispensary at Bellary, described the occurrence of a considerable black deposit, much resembling fragments of coal, in a foot which had been amputated because it was affected by a disease which was commonly known as 'ulcus grave,' because the ulcers and sinuses produced such a serious condition that amputation became necessary. This disease he had described in the same report for the preceding year, designating it 'morbus tuberculosis pedis,' because, though he recognized it to be dissimilar from other recorded diseases, he looked upon it as a local tubercular affection, and, influenced by this view, he considered the black particles mentioned above to be accidental, and not essential parts of the disease. He also mentions that it was known to the natives as 'ghootloo mahdee,' from the tubercular irregularities being supposed to resemble eggs.

This first case of black maduromycosis occurred in a native aged about thirty years, and had existed four to five years before amputation was performed. The morbid appearances are described as being similar to those fully set forth in his 1844 report, with the addition of there being in this instance one cyst (or excavated tubercle) containing melanotic matter about the size of a small walnut, and extending from the plantar to the dorsal aspect of the foot, between the metatarsal bones of the great and second toes, which were in part absorbed. The integuments were not involved in this mass, which when recent had an angular and brilliant black appearance much resembling a fragment of coal, and was considered to be an accidental product in this peculiar case.

Carter says that the second volume of the 'Indian Annals' (probably dated about 1849) on p. 706 contains an account of dark granular or black gritty particles being found among the bones and in the sinuses of a diseased foot, but we have been unable to refer to this work, and are ignorant of the name of the discoverer and of the date and place in which this observation was made. The particles in question were examined microscopically, and were believed to consist entirely of dried blood, a belief which lasted for many years.

It may perhaps be advisable at this point to draw attention to the fact that Ballingall's celebrated observations do not refer to the black, but to the yellow variety of mycetoma, and hence do not enter into this history.

Sub-Assistant Surgeon Bazonji Rustomji (1858), of the Bhoo's Dispensary, in the Province of Kutch, drew attention to the fact that there were two forms of the disease—viz., one in which there was no granular deposit, but only a substance dark in colour and soft and thick in consistence; while the other showed small, soft, yellowish granules. This is the first occasion, as far as we know, when a differentiation was made between the melanoid and the ochroid varieties of the disease, but Rustomji did not recognize the fungal nature of the bodies in question.

Eyre (1860) states that in every foot examined by him there were numerous minute tubercles resembling fish roe, which were found lying beneath the muscles and extending from the bones to beneath the skin, with nodules of the same appearance and often black in colour. This paper deals with the external characters of the disease, its previous history, natural course, morbid anatomy, aetiology (which was doubtfully thought to be somewhat tubercular), and treatment.

In 1860, Vandyke Carter began a series of classical observations upon the black and yellow forms of Madura foot, which he continued until 1874, and during which he firmly established the fungal nature of the disease.

His first paper (1860) was entitled 'On a New and Striking Form of Fungus Disease affecting the Foot and Prevailing Endemically in Many Parts of India.' In his second publication (1860) he clearly differentiated between the white or ochroid division of the Mycetomas, which to-day we call 'actinomycosis,' and the black or melanoid variety, which we now name 'black maduromycosis.' He demonstrated that the black grains were of true vegetal nature, with a black friable rind composed of clear, orange-tinted, ovoid or angular cells and beaded fibres closely arranged so as to form a compact structure, and in addition larger vesicular bodies (seemingly comparable to gemmules or sporangia), which he thinks may arise at the extremities of the compressed beaded fibres by gemmation and expansion. The pale reddish-brown central part of the larger sclerotes was composed of slender, pale, flattened, and branching fibres arranged in bundles and intermixed with numerous granules and a few large beaded fibres, the septa of which were sometimes absent.

He placed some black particles, taken from a foot, on cotton soil moistened with animal juices and enclosed in a stoppered bottle, which he left unopened for two and three-quarter years, when he found a thin reddish film had appeared. Other black particles sown on rice paste for the same length of time remained unchanged, but on opening the bottle a red mould speedily made its appearance.

With reference to this mould, he says: 'It had not, however, a clear connection with the fungus particles, but seemed to spring up independently of them upon the rice whenever this was exposed to the air.'

This statement is of importance, as he grew a fungus from the white variety which was pink in colour, and produced sporangia resembling those of a species of the genus *Mucor* Micheli, 1729, but differing therefrom in the absence of a columella, which should have brought it under the genus *Morticrella* Coemans, 1863; but Berkeley, who examined the growths from a botanical point of view, classified it under the genus *Chionyphe* Thienmann, 1839, calling it *Chionyphe carteri* Berkeley, 1862, and defining it as:—'Hyphasmate ex albo flavorubroque, sporangiis demum coccineis, sporis breviter fusiformibus.'

The genus *Chionyphe*, however, was never recognized by mycologists generally, as its species came under the genera *Mortierella* or *Mucor*, while *Chionyphe carteri* was most undoubtedly a contamination, as its connection with the black or white grains was never proved, as we have noted above with regard to the former.

Thus we may conclude that although Carter gave the first proof of the parasitic nature of the grains, he was unable to produce growths by cultivation from either the black or the white varieties.

In 1860, Minas wrote upon 'keereenagoah' of the foot, as seen in the Punjab. The term used is a vernacular word signifying worm disease. He states that the characteristic symptom of the complaint is gradual enlargement of the foot, usually starting with a swelling in the sole associated with the presence and constant discharge of small particles, either soft or black and hard, from fistulous openings.

Collas (1861) described black maduromycosis as seen in Pondichéry. He recognized the little bodies of blackish or reddish brown colour, which in their clearer parts seemed to be formed of small transparent cells, which he could not sufficiently study. He called the disease 'dégéneration endémique des os du pied.'

H. J. Carter (1862) came to the conclusion that the fungus of black maduromycosis was nearly allied to *Mucor stolonifer* Ehrenberg, 1818, the spores of which in an amœboid state he considered entered the body through the sudorific ducts. Berkeley (1862) mentioned the fungus in question; he gave it the name *Chionyphe carteri*, a nomenclature which he subsequently repeated (1865).

In 1867, Moore reported an important early case, in which he effected a cure by cutting and scraping away all the diseased tissues, and he augmented this in 1873 by recording two more cases of a similar nature, treated in the same way with a like result.

In 1870, Holmsted, of Hyderabad, Sind, found a thorn of irregular shape and ½ inch long in a case of black mycetoma, in which it had been embedded for two years. In the same year, Bristowe described and figured the fungus seen in the black particles of a foot from a case of black maduromycosis amputated in Cantoor, and demonstrated to the Pathological Society of London by Tilbury Fox. Bristowe's descriptions and figures are excellent, and amply confirm Vandyke Carter's work. Thudichum chemically examined the black pigment of this case, and showed that it was not derived from blood.

Hogg (1872) described a black maduromycosis from India, in which he was able to observe the fungal threads and to resolve them into jointed dissepimented cells, some branching out and attaining a considerable length, while others terminated in an enlarged ovoid head. He, however, believed that the fungus was a secondary product, which might greatly aggravate but did not originate the disease, and suggested that it might be introduced at the time of the first accident when the foot was struck against a stone, or by the poultices used as treatment in a later stage.

Vandyke Carter (1874) published his monumental and classical work 'On Mycetoma, or the Fungus Disease of India,' which concluded his long-continued labours at this complaint.

Lewis and Cunningham (1875) admitted the fungal nature of the black particles, but not of the yellow granules. They showed that *Chionyphe carteri* had nothing to do with black or yellow grains.

In 1876, Berkeley came to the conclusion that *Chionyphe carteri* had nothing to do with mycetoma, a point which can be easily judged from the passages quoted above.

Notwithstanding all these researches, a great deal of confusion still existed with regard to the disease, which can be judged by a study of Fox and Farquhar's (1876) report. It was admitted that the black granules were fungal in nature, but it was contended that they were not causal in effect, because all the essential features of mycetoma were found to be present without any black fungal particles, and because there was not sufficient evidence forthcoming at the time in proof of the vegetal character of the yellow grains, which were believed to be essentially fatty in nature. It was, however, admitted that Moore's observation showing that the black variety could be cured by excision of all the particles at an early stage of the disease was a strong argument in favour of the parasitic nature of mycetoma.

Though Carter had found black, yellow or white, and red grains, still the general belief was that these were one and the same process, and, moreover, observers of this period must have seen the pseudomycetomatous conditions mentioned above, because competent workers appear to have met with cases in which they were unable to find any grains, although the clinical appearances resembled mycetoma.

Corre (1883) placed in order, completed, and revised the notes of researches made by Collas since his publication, already mentioned, in 1861. In these notes, which were published after his death, Collas desired his previous name for the disorder to be altered to 'La Maladie de Ballingall,' and states that the earliest references to the disease with which he is acquainted can be found in Waring's paper, and in one of the sacred books of the East which he calls 'Vaweda' (Ushta wunga hrethayum), which appears to us to be the 'Atharvavéda.' In this latter work, 'slipatham,' or elephant foot, is distinguished from 'padavalmicum,' which refers to an incurable malady of the foot associated with swelling and the formation of fleshy tumours, from which, about a year after the appearance of the first symptoms, there exudes a peculiar fluid. He also points out that the words 'perikal,' 'anaikal' (Tamil: this means Cochin leg —'slipada' (Bengalese), 'hatty ka-poung' (Deccan), are applicable to elephantiasis as well as to Madura foot, and, therefore, should not be specially applied to the latter, as they really mean the 'leg of an elephant.' In Ballary, he says, the disease was called 'gootloo mahdee,' because the swellings on the foot were thought to be like eggs; while in Rajputana it was called 'krimagras,' or the dwelling-house of worms, because the sinuses were considered to be like the cavities often occupied by the larvæ of flies. He also says that in 1714 a missionary described under the name of "fourmilière des vers' a disease of Pondichéry which was incurable, and in which numerous ulcers intercommunicated by means of small canals full of worms, which were peculiar in that if one closed another opened. This information Collas obtained from vol. ii., p. 167, of a book published in Paris in 1812, and entitled 'Mémoires sur les mœurs et coutumes de l'Inde par un missionaire.' Collas also points out that in 1806 Heyne saw the brother of a Rajah at Cuddapah in Hyderabad with a foot in a leprotic state, but which was considered to be distinct from leprosy, although it was not known what the nature of the disease might be. Collas thinks that this must have been mycetoma, and draws attention to Brett's 'sarcomes adipeux,' in which he says it is difficult not to recognize Ballingall's disease.

With reference to the above names, it will be noted that they apply to any form of mycetoma, and not especially to black mycetoma. The name 'Ballingall's disease,' in our opinion, is not applicable to the black mycetomas, because, as already indicated, he was not acquainted with the disease.

In 1886, Carter gave up his pink mould, and drew attention to the similarity between the fungus of actinomycosis and that of mycetoma.

Kanthack (1893) studied both the yellow and black mycetomas, and came to the conclusion that the former agreed morphologically and structurally with actinomycosis, but with regard to the black grains his position was curious, for although he found them to consist of an olive-brown, glassy, or finely granular material, in which hollow filaments, radially arranged, were embedded, still he regarded these as degeneration changes, and sought to prove that the granules were an organism allied to the actinomycosis fungus which he had found in the yellow variety. Thus, like Vandyke Carter, he believed both varieties to be fungal in nature and to be caused by the same fungus, but he attempted to show that the fungus of the yellow variety existed in the black, while the former observer believed the reverse to be true. He named the fungus *Oöspora indica* Kanthack, 1893, and distinguished the two varieties as *O. indica* var. *flava* and *O. indica* var. *nigra*. Unna, to whom he sent specimens, however, did not make this error, but says:- 'A whole series of important distinctions separate the two fungi, and there is no question of their identity.'

Boyce and Surveyor (1894), in a most important paper, first definitely proved that the fungi existing in the black and yellow varieties were quite different, and thus definitely established the two main divisions of mycetoma, which to day we call maduromycosis and actinomycosis. They showed that the black grains were composed of a large, septate, branching fungus embedded in a brown pigmented ground substance, which was readily bleached by eau de Javelle. They did not observe spore formation, nor was cultivation attempted.

In the same year Boccaro also differentiated between the white and the black varieties of the disease.

Chatterjee (1911) observed that grains placed in agar and glucose agar tubes increased in size some seven to eight times in four days, and were surrounded by fine hair-like structures which were composed of delicate branching mycelial threads, which were seen to come from the thick black threads. On potato, the growth was dry and black. In broth, small white colonies composed of radiating threads were found sticking to the walls of the tube. No diffuse growth was seen, nor did any scum form on the surface. Animal experiments were negative.

Mackenzie, in the same year, appeared to obtain similar cultures on agar: at first the growth was white and translucent, with radiations from the centre, later it became greyish yellow, there being a central granule surrounded by a clear zone and an indented margin. After a week the colony became a deep mahogany, and under the microscope exhibited mycelial structures.

Semon (1915) reported a case of black maduromycosis which occurred in a native Indian soldier serving in France. He left India about October, 1914, and in January, 1915, he injured one of his feet by the fall of an ammunition box. The patient attributed the disease to this cause, but Semon considers, probably correctly, that he must have been infected before leaving India. A typical mycetoma developed in about six months, and the pus contained black particles in which a central mass of mycelium obscured entirely by black pigment could be made out, but no proper demonstration of the fungus *in situ* could be made The foot could not be amputated, but sections were made of some of the tissue, which showed marked vascular hypertrophy, polymorphonuclear, plasma, and connective tissue cells, but no endo- or periarteritis and no giant cells. Growths were obtained at 35 C. on agar-agar, maltose agar, and Raulin's fluid. The fungus formed a central black portion with a peripheral zone of white or grey, and in the course of ten days or less became black

In 1916 Chalmers and Archibald grew a fungus allied to that described by Semon from a case of black maduromycosis found in the Anglo-Egyptian Sudan, and in 1918 defined and classified the Maduromycoses.

Climatology.- The Maduromycoses are known to occur in Europe, Africa, Asia, and America, but not in Oceania.

The climatology has been most thoroughly studied for black maduromycosis, which occurs in the Anglo-Egyptian Sudan, where the disease was first described by Balfour in 1904, and the northern part of which is hot and arid. He gives the native name for mycetoma as 'Napt Hindi Nabit,' and states that the black variety is most frequently encountered, and that the foot is the part principally affected, while the inguinal glands are often involved. In 1908, Wenyon noted its presence at Bor, which is hot but not arid, while Balfour's researches in 1911 have already been noted in the historical section. According to our inquiries, the word most commonly used by natives in the Sudan is 'en-nabt,' which means 'the growth.'

In addition to the Anglo Egyptian Sudan, the following is a list of African places from which cases of black maduromycosis have been reported: Algeria, Tunisia, Somaliland, Madagascar, Transkei (South Africa), Senegal, and the French Sudan.

In Asia the disease is recorded from the Yemen, various parts of India, Ceylon, and possibly from North Borneo.

In America it has been described in the United States by Wright, and in the West Indies by Scheult.

In Europe it has so far only been found in Italy, Macedonia, and Southern Germany.

This distribution, according to political geography, has but little meaning when the object being studied is a fungus, and for further details we turn to plant geography. According to Drude, climatic and local conditions permit the division of the surface of the world into six zones of vegetation, viz.:—The Northern Glacial Zone, the Northern Cold Winter Zone, the Northern Hot Summer Zone, the Tropical Zone, the Southern Hot Summer Zone, and the Southern Cold Zone.

The black maduromycoses occur in the Northern Hot Summer Zone, which includes Spain and Italy, North America, the Sahara, Indo-China, Malay Archipelago, the United States (roughly south of Utah), and Mexico. The general characters of this region are:—Very hot summer temperatures with cold nights and no real winter, but with varying rainfall. It contains very dry climates: it also contains wet areas. The black maduromycoses are most commonly met with in the dry parts of this area

The Tropical Zone, which appears to be the real home of these fungi, is generally humid, but contains arid regions bordering upon the preceding. In this zone comes the Anglo-Egyptian Sudan, in the northern or more arid part of which black maduromycoses are common, and the same remarks apply to Somaliland, while West Africa is mostly moist.

It also includes the greater part of India, in which the distribution of mycetoma, according to Boccaro, is interesting.

This observer states that Major Prain divided India into six floral regions, viz.: India Deserta, India Diluvia, India Aquosa, India Vera, India Sub-Aquosa, and India Littorea, while black maduromycosis is found in only India Deserta and India Vera, and is practically almost absent in other regions.

India Deserta includes the Indus Plain Region—*i.e.*, Sind, Rajputana, and the Punjab: while India Vera includes the Deccan Region, consisting of the dry but not desert triangle between the Western and Eastern Ghats, with its apex at Tinnevelly and its base at the borders of the plain of the Ganges.

The white varieties of mycetoma are also found in this area, but are outnumbered by the black maduromycosis, while in India Deserta the preponderance of the black maduromycoses is even more marked than in India Vera.

In Madura and adjoining districts of Tinnevelly, Palmcotta, and Coimbatore, situate in India Vera, mycetoma is very common, and the climate is hot and arid.

The Southern Hot Summer Zone includes South Africa, where the disease has been recorded, but where it is apparently rare.

This is as far as the present state of our knowledge permits us to go with regard to geographical distribution, and more research on this part of the subject is required, but from the above it is obvious that heat and aridity are favourable conditions for the fungi which cause black maduromycosis.

Botanical and Zoological Distribution.—Unfortunately, we are in complete darkness as to the characters which the fungi causing black maduromycosis assume when not living in animals or on artificial culture media.

Even with regard to those forms of black maduromycosis due to an aspergillus, we are quite ignorant as to whether this particular fungus lives on soil or on plants.

Ætiology.—The outstanding feature of microscopical specimens prepared from a case of maduromycosis is the presence of coloured granules, black in *black maduromycosis*, whitish or yellowish in *white or yellow maduromycosis*, and red in *red maduromycosis*.

These coloured granules are called 'grains,' a term which has been defined by Chalmers and Archibald as follows:—

'The term "granum" or grain has been given to differently coloured bodies of varying consistence, size, and shape, found in mycetomas, and composed of hyphæ, with sometimes chlamydospores, embedded in a matrix and giving rise to mycelial filaments on germination.'

The ætiological importance of these grains and their contained fungus rests upon the fact that they are present in all forms of maduromycosis and are co-extensive with the disease, while their complete removal effects a rapid and complete cure.

Animal inoculations have been successful in some varieties, thus affording, in these instances, a full and convincing proof of the ætiology of the fungus—*e.g.*, Pinoy's and Pepere's varieties.

The ætiological features of the various forms of maduromycosis are set forth below in a list which shows the Maduromycoses classified —firstly, by the colour of the grain; secondly, by the geographical distribution; and thirdly, by the discoverer's name or names.

I. The *black maduromycoses*, with black grains.

II. The *white or yellow maduromycoses*, with white or yellowish grains.

III. The *red maduromycoses*, with red grains.

I. THE BLACK MADUROMYCOSES.

These may be divided into:—

A. The *European black maduromycoses.*
B. The *African black maduromycoses.*
C. The *Asian black maduromycosis.*
D. The *American black maduromycoses.*

A. THE EUROPEAN BLACK MADUROMYCOSES.

(1) *Bassini's*, *Kölner's*, and *Schmincke's black maduromycoses*, respectively found in Padua, Italy, and in Kissingen, and of which the nature of the ætiological fungus is unknown.

(2) *Bovo's black maduromycosis*, found in Genoa, and of which the causal agent is called *Madurella bovoi* Brumpt, 1910, but this identification must be accepted with reserve, as the fungus has never been cultivated, and may not agree with the definition of the genus Madurella, as altered by Pinoy in 1912 subsequent to the cultivation of *M. mycetomi* and *M. tozeuri*.

(3) *Pepere's black maduromycosis*, found at Domusnovas in the Province of Cagliari in Sardinia, and caused by *Scedosporium sclerotiale* Pepere, 1914.

B. THE AFRICAN BLACK MADUROMYCOSES.

(1) *Brumpt's black maduromycosis*, caused by *Madurella mycetomi* (Laveran, 1902).

(2) *Nicolle and Pinoy's black maduromycosis*, caused by *Madurella tozeuri* (Nicolle and Pinoy, 1908).

(3) *Bouffard's black maduromycosis*, caused by *Aspergillus bouffardi* Brumpt, 1905.

(4) *Chalmers and Archibald's black maduromycosis*, caused by *Glenospora khartoumensis* Chalmers and Archibald, 1916, which has now been recovered three times in the Anglo-Egyptian Sudan.

These African black maduromycoses may be differentiated from one another as follows:—

A. Microscopical preparations show aspergillar heads—*Bouffard's black maduromycosis.*
B. Microscopical preparations do not show aspergillar heads; on culture the following types of spore are obtained:—
  1. The aleuriosporal form of conidium—*Chalmers and Archibald's black maduromycosis.*
  2. The arthrosporal form of thallospore.—
    (*a*) Mycelium greyish-white, when old, yellowish and darkening the media in sugar cultures. Spores varying in dimension from 2 to 5 microns. Grains black and sterile, with a diameter from 0·5 to 1 millimetre, formed in the depths of the medium in cultures. Can invade the skin, bone, muscles and connective tissue of man, giving rise to black grains which are small, hard, round, and more or less warty, and which morphologically resemble the grains formed in the cultures. Up to the present the inoculation into animals is negative. Very widely spread in Africa. Isolated by Brault from a mycetoma with black grains in Algeria—*Brumpt's black maduromycosis.*
    (*b*) Mycelium white, becoming yellowish with age, and darkening the medium in sugar cultures. Spores generally small, 2 microns or sometimes even 5 microns in diameter. Grains are only rarely produced, and then they appear on the surface of the medium. Occasionally it gives rise to a mycetoma in man, in which it forms black amorphous grains which are often made up of mycelial rings enclosing some degenerate cellular elements which are impregnated with the pigment of the fungus, and also of small diffuse masses formed solely by the filaments of the fungus which have a yellow membrane. Inoculation into pigeons positive. Isolated by Nicolle from a mycetoma at Tozeur—*Nicolle and Pinoy's black maduromycosis.*

C. The Asian Black Maduromycosis.

There is only one type known at present—viz., *Carter's black maduromycosis*, caused by *Glenospora semoni* Chalmers and Archibald, 1917, which can be readily differentiated from *Glenospora khartoumensis* Chalmers and Archibald, 1916, by the following characters:—

(1) Grown on clear maltose agar in Khartoum after twelve days in an uncapped tube at 30° C.:—

G. semoni produces a cupola-shaped, large, central black mass with an outlying fringe of white.

G. khartoumensis produces a black growth, consisting of a central crumpled ridge or hillock placed on a grooved black plateau, and with hardly any white fringe.

(2) and (3) Grown on glucose agar and blood serum; there are marked differences between the two fungi.

D. The American Black Maduromycoses.

(1) *Wright's black maduromycosis*, which was found in the United States in an Italian woman who had left Italy, where black maduromycosis occurs, an indefinite number of years before the onset of the malady. The systemic position of the causal fungus is unknown.

(2) *Scheult's black maduromycosis*, which was found in the West Indies in a native of India, who had left that country twelve years before the onset of the malady. The nature of the causal organism is unknown.

II. THE WHITE OR YELLOW MADUROMYCOSES.

These may be divided into:—

A. The *European white maduromycoses*.
B. The *African white maduromycosis*.
C. The *Asian white maduromycosis*.

A. The European White Maduromycoses.

(1) *Brumpt and Reynier's white maduromycosis*, caused by *Indiella reynieri* Brumpt, 1906, with a large *soft* grain, found in Paris.

(2) *Tarozzi and Radaeli's white maduromycosis*, caused by *Scedosporium apiospermum* (Saccardo, 1911), with a small, *rather hard*, and yellowish grain, found in Sardinia and Italy.

B. The African White Maduromycosis.

Nicolle and Pinoy's white maduromycosis, due to *Sterigmatocystis nidulans* (Eidam, 1883), with grains of size varying from those which are almost microscopic to others about the size of a pea, of rounded or polyhedral form, and of variable colour, being dirty white or yellowish-white, and *soft* in consistence, and found in Tunisia.

C. THE ASIAN WHITE MADUROMYCOSIS.

Brumpt's white maduromycosis, due to *Indiella mansoni* Brumpt, 1905, with very small and very hard white grains, found in India.

The differentiation of the white maduromycoses may be effected as follows:—

A. *Grains soft*:—
  1. Sterigmatocystic heads found in grains and in cultures. Grains *not* like a ribbon rolled on itself—*Nicolle and Pinoy's white maduromycosis*.
  2. No such heads to be found in the grains, which are like a ribbon rolled upon itself—*Brumpt and Reynier's white maduromycosis*.

B. *Grains hard*:—
  1. Grains small, yellowish, not reniform; spore of the type of a conidium—*Tarozzi and Radaeli's white maduromycosis*.
  2. Grains small, whitish, reniform; spore of the type of an arthrospore—*Brumpt's white maduromycosis*.

III. THE RED MADUROMYCOSIS.

Only one form is known *Balfour and Archibald's red maduromycosis*, which was possibly due to an aspergillus, because aspergillar like heads were found in the grains It occurred in the Anglo-Egyptian Sudan

Pathology.—The causal fungus is introduced into some part of the body by a wound produced by a thorn, a splinter of bamboo or other wood, by a sharp stone, knife, etc., but once introduced into the subcutaneous tissues, it commences to grow, the original wound in the meantime healing. Usually the growth is slow; but if Kemper and Jamieson's case was true mycetoma, it may be rapid, and, indeed, this is supported by Musgrave and Clegg's inoculation of *Nocardia asteroides* into a monkey's feet, in which the swelling developed in ten to sixteen days, and was quickly followed by suppurative lesions. As the fungus grows, it destroys the tissues of the foot, and meets with but little reaction on the part of the body, and no attempt is made to repair its ravages. The reaction on the part of the body confines itself to a lymphocytic infiltration around the fungus, and later the formation of granulation tissue, with epithelioid and giant cells at times; while, finally, fibrous tissue is formed around the fungus and its surrounding cells, and the vessels become blocked by an endarteritis and periarteritis. This appears to be an attempt to encapsule and prevent the spread of the parasite, as well as to damage it by cutting off its food-supply.

At the same time the cellular exudate becomes a thin, oily, occasionally stinking, pus, and works its way to the surface, forming apertures, and carrying the parasite with it. This must be considered to be an attempt to rid the body of the fungus.

In the meanwhile the parasite, if of certain species, forms special club-shaped hyphæ considered to be chlamydospores, which at first serve for extracting nutrition from the surrounding leucocytes, but later, breaking free from the main mass, form means of asexually propagating the fungus in the foot. Some of these separated clubs are attacked and engulfed by leucocytes, and though it is possible that in this way many may be destroyed, still, Brumpt's researches show that the leucocyte, with its enclosed club, may wander away from the diseased area into healthy tissue, and may be killed by the club, which, being set free, grows into a new mass of fungus. In this way the fungus may be disseminated by means of the phagocytes.

When surrounded by pus, the fungus gathers itself into granules, the so-called sclerotia, which show externally radially arranged fibres or clubs, and internally a mass of mycelium with crystals and débris, the latter being most marked in the centre. These granules escape to the exterior, and form the yellow, black, or pink granules in the discharge. As the fungus grows in the foot the connective tissues and the muscles undergo vitreous degeneration, and break up into débris, amongst which pieces of nerves and tendons may be found, while even the bone in some cases becomes attacked by a form of degeneration and disappears. The result is that the foot appears much swollen externally, and shows the openings of the sinuses, through which the pus and the fungoid granules escape; while internally the normal structure may have completely disappeared, being replaced by degenerated tissue, débris, sinuses, and fibrous sacs containing the fungus and the pus.

The result is, however, not merely destruction of the foot, but also great bodily waste, due to the continuous discharge, so that the patient becomes emaciated, and may finally die of cachexia.

Morbid Anatomy.—The pathological anatomy of black maduromycosis has been the subject of a fair amount of investigation. Kanthack merely drew attention to the fact that the black masses were always to be found embedded in dense fibrous tissue, while a few pus and granulation cells were to be seen in most cases. In the fibrous wall yellowish-brown or black pigment could be found, while fuchsin bodies were present in most specimens. Unna's example, obtained from Kanthack, only showed fibrous and some granulation tissue. Boyce and Surveyor drew attention to the presence of small round cells, macrocytes, and giant cells surrounding the fungus in cases of black maduromycosis. Their microphotographs are, however, mainly devoted to the fungus, while their Fig. 22 evidently depicts a very young piece of fungus surrounded by giant cells.

Wright (1898) stated that the nodules consisted of more or less atypical connective tissue, in the cavities of which the granules lay surrounded by polymorphonuclear leucocytes, loose epithelioid cells, and cellular detritus. The cavities were lined by either a wall of vascular granulation tissue or by masses of epithelioid and multinucleated giant cells, while these cells closely invested other granules, and outside of this tissue lay lymphoid and plasma cells. He gives in his original paper four excellent low-power photographs, of which

Figs. 4, 5, and 6, though older, if examined with a lens, will be seen to agree more or less with Boyce and Surveyor's Fig. 22.

Oppenheim's description in 1904 mainly deals with the fungus, but Brumpt's account of the histological changes induced by *Aspergillus bouffardi* covers all the important points—viz., the polymorphonuclear leucocytes, the lymphocytes, the giant and epithelioid cells, the connective tissue, the cells containing brown pigment, and the endarteritis. On Plate XIX., Fig. 7, and Plate XX., Figs. 1 and 2, he shows appearances resembling those described by Boyce, Surveyor, and Wright in a young grain in which the giant cells are situate close to the fungus.

Boccaro, writing in 1909 in general terms for the encapsulated form of both white and black mycetomas, says:—

> 'The fungal hyphæ are surrounded by round cells, held together by a delicate network of fine bloodvessels, the cells being located in the meshes of a fibrillar, transparent, reticulated substance. On the inner side of the group of round cells, between them and the central hyphal mass, is a collection of *finely granulated débris*, and on the outer side, in most preparations, may be seen large nucleated cells, giant cells, and phagocytes.'

This description, which unfortunately is not illustrated, agrees well with our observations.

Balfour, in 1911, published photomicrographs of black maduromycoses believed to be due to *Madurella mycetomi* and to *Aspergillus bouffardi*, but did not describe them.

Babès (1913) gave a well-illustrated account of Indian black maduromycosis, in which he observed far less cells than we have noticed in immediate relationship to the fungus, from which the giant cells were separated by fibrous connective tissue. He drew attention to violet and reddish rounded bodies enclosed in cells.

In 1916 Chalmers and Archibald gave an account of the histology of a case of black maduromycosis, and this is followed in the description given below.

Fig. 845 shows the general appearance of black maduromycosis very slightly magnified. It will be observed to be largely composed of fibrous tissue containing black particles—the grains—and some spaces, which are formed by the falling out of some of the black granules during preparation. The spaces demonstrate the character of the lacunæ occupied by the grains and their surrounding cells.

FIG. 845.
BLACK MADUROMYCOSIS.

The fungal mass lies embedded in cellular tissue, as is shown in Fig. 846. The spaces are artefacts produced in making the section, which otherwise is as natural as possible—*i.e.*, is not bleached or softened in any way. The cracks in the black mass are also artefacts. Around the fungus lies a mass of small cells, and on the upper and left side of the grain are seen some giant cells, which also occur in other parts, but are not in such close relationship to the fungus; then comes some fibrous tissue containing a number of cells, bloodvessels, and lymph spaces, the last mentioned being situate towards the top of the photograph and being markedly dilated. At the very top of the figure, and only partially shown, comes the dense fibrous connective tissue which is continuous with

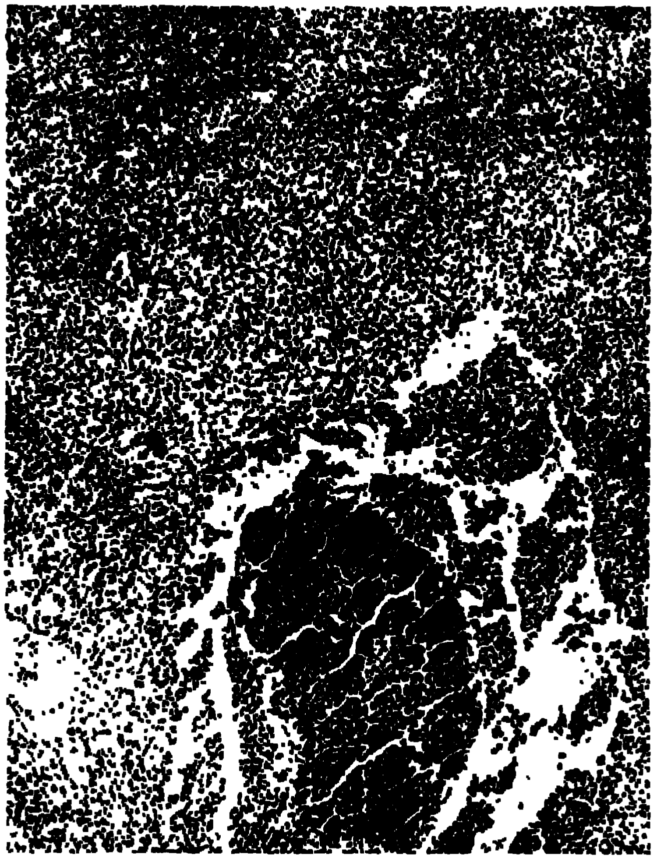

FIG. 846.—BLACK MADUROMYCOSIS

the dense tissue, depicted in Fig. 846, which permeates and surrounds the growth. Therefore the main features of the tumour may be summarized as follows:—

1. Fungus.
2. Small cells.
3. Giant cells and large cells.
4. Small cells, connective tissue, bloodvessels, and lymph spaces.
5. Dense connective tissue.

The cells are separated by a variable amount of fine connective tissue, which also supports large lymph spaces and bloodvessels. Débris and pigmentary granules can also be seen. A special rare feature of this layer is the presence of mononuclear cells containing one or more eosinophile rounded bodies, which were first observed in this pathological condition by Kanthack, and subsequently by nearly all the other workers on the morbid histology of the black maduromycoses, to which they are, however, not confined. Their exact nature is unknown, but they are probably in some way due to the fungus.

On inspecting the upper part of the cellular mass, it will be observed that the white fibrous tissue increases in amount, but is still loose and contains many cells in its meshes, while more externally, and situate at the top of the photograph, is seen the denser and less cellular connective tissue, which is continuous with that separating one fungal mass from another and surrounding the whole tumour. In this connective tissue, cells containing yellowish granules are frequently observed.

There are also many lymph spaces and bloodvessels, but the latter at times show signs of endarteritis or periarteritis, by which means the lumen of the vessel may be considerably diminished or even closed.

Very rarely do the fungi invade the body, and rise to a general infection.

The peculiarity of the pathology is the slight reaction which the body makes against the invasion by the fungus, and the entire absence of any attempt at repair.

The black varieties of mycetoma owe their colour to a dark substance which the fungi secrete. The nature of this black substance is not known. It is soluble in hot sulphuric acid, forming a yellowish-red solution, but is not soluble in cold sulphuric acid nor in potash solutions. According to Thudichum, it does not contain hæmoglobin in any form, though a small quantity of iron is present.

In more advanced cases the swollen foot shows nodules and openings externally, the latter of which lead into the sinuses. In sectionizing the foot it will be noticed that the sinuses which run in various directions are communicating, and end in small cavities containing pus and the fungus, and that these cavities are embedded in degenerated tissue and débris.

The bone may or may not be affected, but if it is, the whole foot can be easily cut by a knife.

Microscopically the tissues show degeneration and débris, with fibrous tissue formation, endarteritis, and periarteritis, and at times absorption of the bone.

The microscopical examination of sections of the tissues typically affected—viz., of alveolar appearance--and containing mycotic grains, show a central roundish mass—the mycotic grain– a clear circular space, and the surrounding degenerated tissues. The clear space is due to the fact that the thin purulent matter in which the granule is embedded contracts during fixation with alcohol. The mycotic granule is composed at the centre almost exclusively of mycelial elements with a few leucocytes; more externally there are masses of amorphous substance, staining lightly purplish with eosin, in which a few mycelial threads may be seen. The periphery shows a polymorphonuclear infiltration. The walls of the alveolar cavities containing the granules are formed of young connective tissue with numerous plasma cells and occasionally giant cells; there is a marked proliferation of bloodvessels.

Symptomatology.—The disease usually begins in the foot, more rarely in the hand, and still more rarely in the leg, knee, neck, or trunk. There may or may not be a history of a cut or injury some time previously. In any case, this primary injury will have healed long before the disease is well established.

The incubation period in well-recorded cases would appear to be short; thus, in Musgrave and Clegg's case, one month after the primary injury the wound reop[illegible]l and discharged pus, and in their experiments on monkeys [illegible]ppeared to vary from ten to sixteen days. Further researc[illegible] on this point are, however, required.

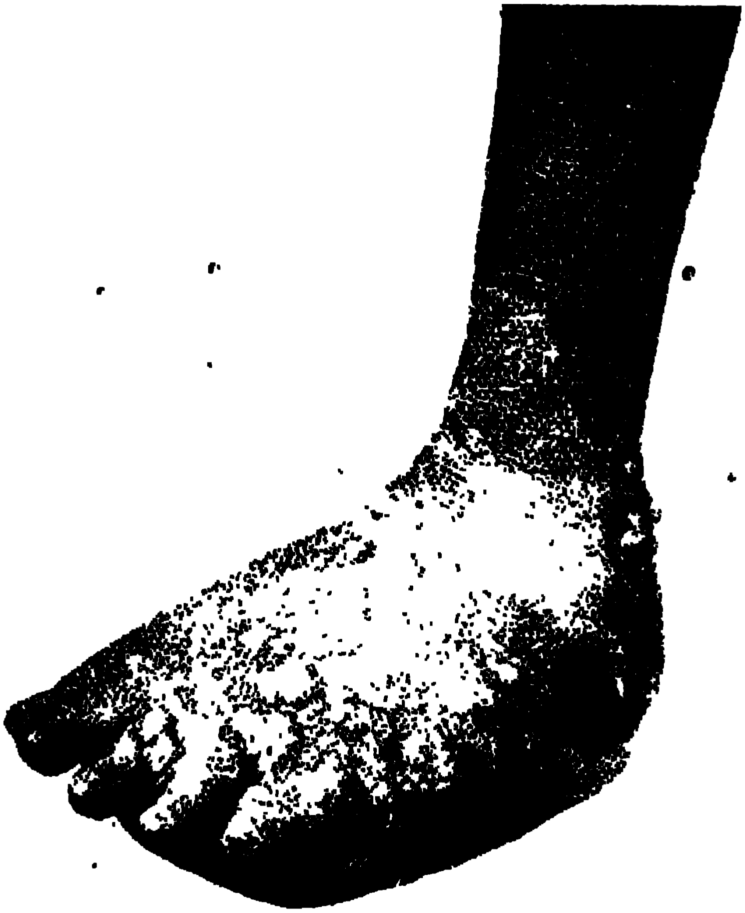

FIG. 847.- MYCETOMA.

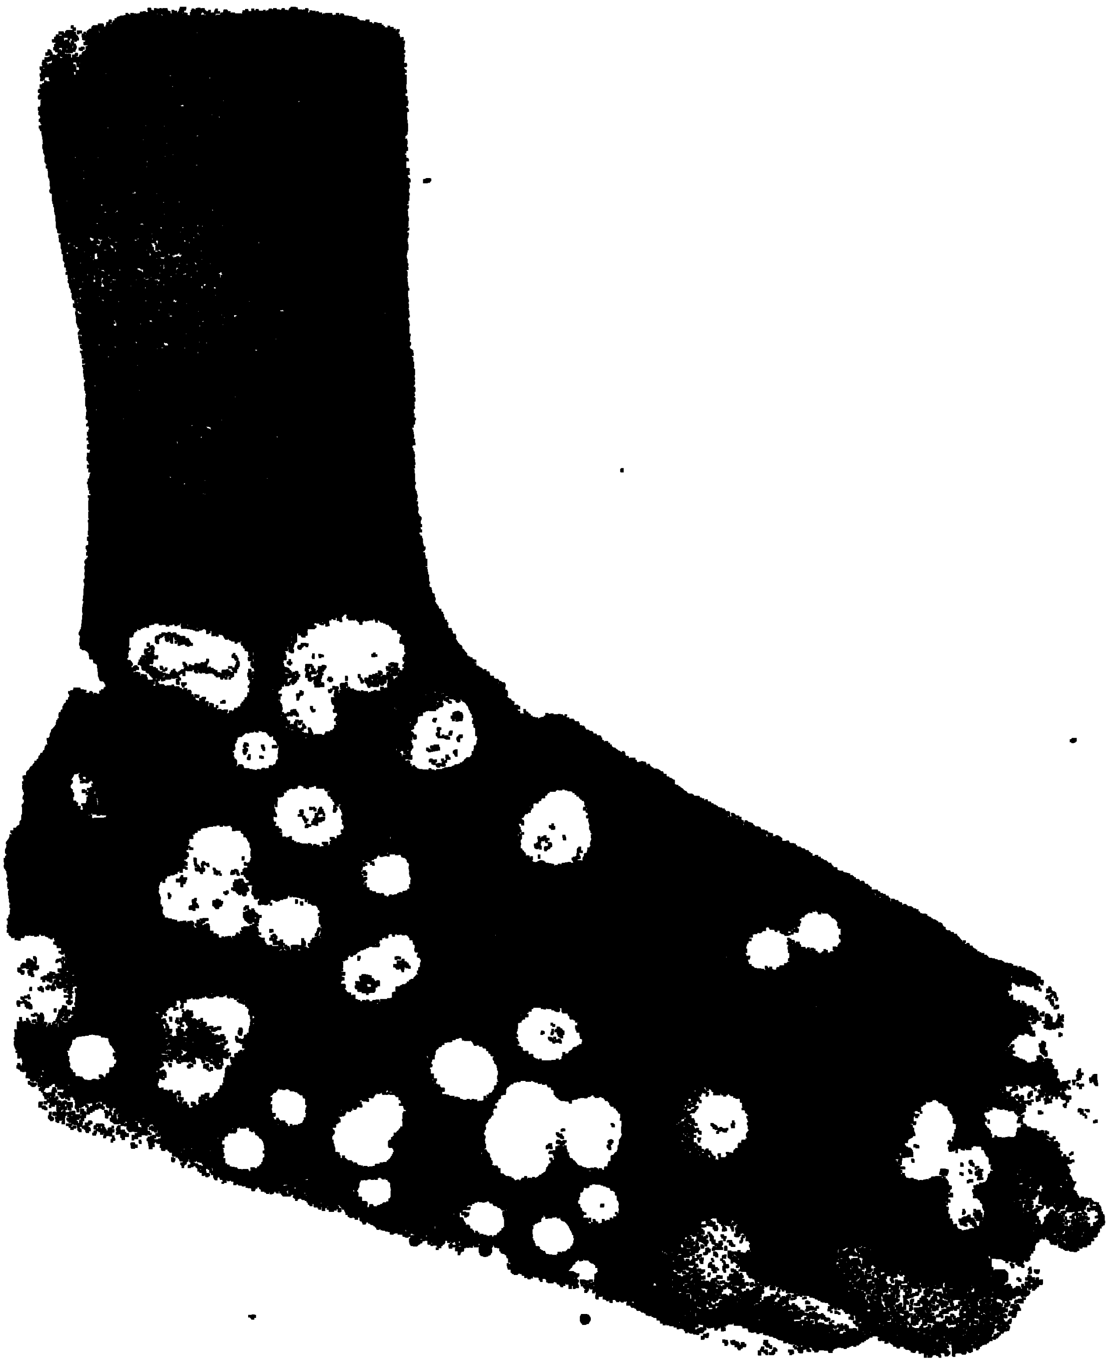
The earliest signs are either pain or swelling in the region of the original injury, which is usually on the sole of the foot, between the toes, or on the instep. The swelling becomes a hard lump, on the surface of which a bleb may form, which bursts and reveals a small opening discharging an oily, rarely sanious, thin, offensive pus, in which the granules characteristic of the fungus may be found.

PLATE XIII.



MYCETOMA.

Some new indurations and nodosities appear in various parts of the foot, and new openings are formed, while the whole foot begins to swell in a very characteristic manner. First the arch of the foot fills up and disappears, the whole sole becoming so swollen and convex that the toes are no longer able to touch the ground, and may be pushed apart, but are usually not affected by the disease. At the same time the dorsum of the foot becomes studded with nodules and openings. The colour of the integument may be normal, but is usually darker than in the healthy skin. It is rarely œdematous. The openings, when examined by a probe, are found to lead into sinuses, which penetrate deeply into the tissues, and at times even into the bones of the foot. The quantity of the discharge varies from time to time, being increased by motion. On palpating the affected area, it is found to be elastic, and the sensibility to be normal. The inguinal glands are often enlarged and hard.

As the disease progresses, pain, which at first was slight, becomes more marked, especially in cold weather. The patient ceases to be able to place the foot to the ground, and is compelled either to walk on the heel or to use a support. The leg begins to waste, and after a long time the patient becomes weak and anæmic from the constant drain on the system by the discharge, and possibly also by toxins produced by the fungi. General constitutional disturbance of a febrile nature is rare.

The disease is very chronic, and has no tendency to heal, and if not treated, will eventually cause the death of the victim, from exhaustion or diarrhœa, after lasting some ten or twelve years.

Diagnosis.—The peculiar swelling of the foot, with a filling-up of the arch, and the formation of sinuses from which a discharge containing the typical grains is escaping, enables the disease to be diagnosed with certainty from elephantiasis or tubercular disease of the foot.

The variety of the fungus may be determined by examining the grains or the scrapings of the sinuses microscopically, culturally, and by inoculations in animals.

It is to be noted that the typical grains may for a time be absent from the purulent liquid exuding from the sinuses. In such cases squeezing of the nodules may make the grains appear, or a nodule which has not yet opened may be incised and the contents examined.

Prognosis.—If the growth is observed when young, small, and lying subcutaneously, so that it can be completely removed, the prognosis is good, as the wound heals readily and the growth does not recur.

If, however, the growth has lasted some time, and has involved the bones, the prognosis is not good, and is worse if the lymphatic glands are also implicated.

Treatment.—Remove the growths at an early stage and as completely as possible. In later stages amputations well above the seat of any lesion, together with the removal of any enlarged lymphatic glands, is the only possible treatment.

Potassium iodide may be tried, but as a rule internal medicines and vaccines are useless for this form of mycetoma.

Prophylaxis.—The wearing of boots and shoes and not walking barefoot are apparently good and sensible methods of prophylaxis.

THE ACTINOMYCOSES.

Definition.—The Actinomycoses are those forms of mycetoma with grains composed of very fine non-segmented mycelial filaments, in which usually the walls are not clearly defined from the contents, and in which chlamydospores are absent.

History.—This period opens with Bollinger's epoch-making work in 1876 on the lumpy-jaw of cattle, a disease which had been recognized since 1785, and in which he found the constant presence of a branching organism. This fungus was examined by Harz (1877-78), who gave it the name *Actinomyces bovis*, but, most unfortunately, this generic name cannot stand, because, unbeknown to Harz, it had already been used by Meyen (1827) for a fungus which he called *Actinomyces horkelii*, which is in no way related to the group of fungi which we are considering. This mistake launched the generic name applicable to these organisms on to a sea of change, and led to much confusion.

1. *Nocardia bovis*.—The correct name for Bollinger's organism is *Nocardia bovis* (Harz, 1877). The fungus appears to have been first seen in man by Israel in 1878. Corre (1883) was the first to draw attention to the similarity between actinomycosis and the ochroid variety of mycetoma, while Acland (1886) was the second observer to demonstrate the presence of actinomycosis in man; and as Israel's name is associated with quite a different human actinomycosis, we propose to name this variety *Acland's actinomycosis*. In 1886, Vandyke Carter, as we have already stated, also drew attention to the likeness between actinomycosis and mycetoma. Finally, in 1891, Bostroem grew *N. bovis* from eleven cases of actinomycosis in man, and since that time it has often been cultivated and described. It is a *nocardia* with radially arranged filaments, which show club-like enlargements of their extremities, caused by a protective thickening of the walls in animals and less commonly in man, and having abundant Gram-positive but not acid-fast hyphæ, some of which end in chains of arthrospores.

It grows well aerobically at 22° C., but better at 37° C. Anaerobic growths are, as a rule, but poorly developed.

It may form a dry pellicle on the surface of broth, but more usually it gives rise to cohering colonies at the bottom of the tube, and in either case the medium remains clear.

It grows slowly on gelatine, producing a yellowish-white growth and slow liquefaction, beginning about the seventh day. The resulting fluid may or may not be dark coloured. On blood serum it produces poor growths, and no liquefaction or pigmentation of the medium.

On agar and glycerine agar it forms hard, spherical, white colonies, which give rise to an undulating crateriform growth, having a yellowish or greyish tint, which in its turn becomes a lichenoid ashen grey or yellowish mass with a powdery efflorescence. On maltose agar it forms discrete fawn-coloured colonies, later becoming yellow, dark brown, or even black, while the medium may be slightly darkened.

On potato it forms confluent, hard, raised, variously coloured masses, at first white, but becoming greenish-yellow, brown, greyish-black, or even black, with more or less erosion and pigmentation of the medium to which the growth is very adherent. No diastatic action has been observed.

Litmus milk is first reddened, but later it becomes a clear brown alkaline liquid. It is pathogenic for man, ox, horse, pig, and other animals, while experimentally rabbits and guinea-pigs have been infected by intraperitoneal inoculation.

2. *Nocardia asteroides.—Nocardia bovis* (Harz, 1877) is not the only organism known to cause actinomycosis in man, for in 1890 Eppinger obtained an organism which he called *Cladothrix asteroides*, and which is now known as *Nocardia asteroides* (Eppinger, 1890), from the lesions in a case of pseudo-tuberculosis of the lungs and pleura, with old caseous nodules in the apices and calcareous degeneration of the bronchial and supraclavicular glands, together with a cerebral abscess which had ruptured into the ventricles. The fungus was Gram-positive and acid, but not alcohol-fast, and grew aerobically on laboratory media, and was pathogenic for laboratory animals. It was afterwards recognized by Almquist, in 1890; by Sabrazès and Rivière, in 1894; by Aoyama and Miyamoto, in 1900, in Tokio; by MacCallum, in 1902, in America; and by Schabad, in 1903, in Russia. It is also the same as the fungus described by Musgrave and Clegg (1907), in a case of mycetoma in the Philippine Islands, under the name *Streptothrix freeri*.

In 1909, Lindenberg, in Brazil, isolated a fungus from a case of mycetoma of the left leg, which began in the popliteal space, and to this organism he gave the name *Discomyces brasiliensis*.

He was very careful to separate it from *N. bovis* and from *N. maduræ* (*N. indica*), but he does not appear to have done so with regard to *N. asteroides*. We therefore offer a comparison between the two organisms in the table on p. 2132.

The inoculations into animals are not comparable, as Lindenberg did not use monkeys. He was unsuccessful with a guinea-pig, but does not say how he inoculated it, while Musgrave and Clegg were successful by means of intraperitoneal inoculations.

The differences as set forth between *N. brasiliensis* and *N. asteroides* appear to us to be very slight, and therefore we are able to agree with Pinoy in his belief that they are one and the same organism.

Also Cranwell, Bachmann, and Del Pont (1909) gave an excellent and well-illustrated description of a yellow mycetoma in Buenos

Aires. Unfortunately, they did not grow it on inspissated blood serum, but, as far as we understand their account, we should classify this organism, which they did not name, as *Nocardia asteroides*.

Nature of Test.	*N. asteroides from Musgrave and Clegg.*	*N. brasiliensis Lindenberg.*	*Result of Comparison.*
Seat of disease	Mycetoma of foot	Mycetoma of leg	Difference unimportant.
Grains	Consistency dough-like, colour yellowish-white; size 0·25–0·5 mm. in diameter.	Consistency soft, colour yellowish-white; size 0·1–0·5 mm. in diameter.	No important difference.
Clubs	Usually absent.	Absent.	Agree.
Bacillary and coccal forms	Numerous bacillary and coccus-like varieties.	Bacillary and coccal forms present.	Agree.
Optimum temperature	Slower growth at 30° C. than at 37° C.	Better growth at room temperature than at 37° C.	Slight disagreement.
Anaerobic cultivation	Does not grow	Does not grow.	Agree.
Broth	Floating flat particles which later fall to the bottom Medium not affected	Small particles which later fall to the bottom of the tube. Medium not affected	Agree.
Gelatine	No liquefaction	No liquefaction	Agree.
Sabouraud's glucose agar at 37° C.	Centre yellow periphery pink to pinkish white.	Colonies rose violet	Slight disagreement.
Potato	At first delicate pink and later yellow ochre centre with pinkish or white periphery, the medium becomes darkened	At first a rose colour, and later a yellow-orange colour; the medium becomes brown.	Agree.
Serum	Growth slower Colonies at first white, later diffuse pink.	Grows very badly at 37° C. Colonies white.	Later pink not mentioned in *N. brasiliensis.*
Milk	Yellowish mass. No coagulation	Yellowish-orange pellicle. No coagulation.	Agree.

Nocardia asteroides possesses Gram-positive, acid, but not alcohol-fast hyphæ, which are without club-like enlargements. It produces restricted growths aerobically and usually anaerobically at 22° C. and 37° C., but nothing is stated in the literature we have consulted with regard to any odour arising from these cultures. It does not liquefy gelatine or blood serum, nor has it any diastatic action. It reddens litmus milk, which later becomes alkaline, but is not coagulated or cleared. It grows on the agars and on potato, producing reddish (often brick red) growths. It is pathogenic for monkeys, rabbits, and guinea-pigs.

3. *Nocardia liquefaciens.* This fungus was obtained by Hesse in 1892 from a man in Germany with a left inguinal abscess which communicated with the rectum. Subsequently other abscesses formed on either side of the dorsal spine. The pus from these abscesses discharged soft yellowish grains about the size of a millet seed, which contained a Gram-positive fungus which did not possess clubs. On cultivation it grew readily, and was found to be strictly aerobic. In gelatine stabs it formed a nail-shaped growth, which at room temperature in Europe was only visible on the third day, while liquefaction, beginning on the fourth or fifth day, was complete by the end of the week. The liquefied gelatine was not discoloured, and if the growth stuck to the glass it was yellowish, with a whitish covering. On blood serum it formed small cloudy granules of the same colour as the medium, in twenty-four to forty-eight hours. Liquefaction begins at the end of the first week and proceeds slowly, the liquid remaining quite clear and colourless, and only after some six months turning to a reddish-yellow colour. In broth it forms delicate flakes which fall to the bottom of the tube, and consist of a lower surface which is yellowish-white, and an upper surface which is snow white. The medium remains quite clear. No surface growth is mentioned.

On agar the colonies at first form separate rosettes, which remain distinct for a time. These colonies appear to resemble the gelatine culture, being yellowish below and having a white envelope. The growth on glycerine agar is more vigorous than on ordinary agar.

On potato it forms small yellow nodules by the second day, which later become covered with a snow-white efflorescence, which does not alter. Apparently it was not grown on glucose agar, milk, or eggs. Intravenous, intraperitoneal, and subcutaneous injections into rabbits, guinea-pigs, and white mice were negative.

Hesse gave it the name *Cladothrix liquefaciens*, which now becomes *Nocardia liquefaciens* (Hesse, 1892), and it appears to be the same organism as that named *Streptothrix buccalis* by Goadby in 1903, and found by him in 1899 in the mouth in cases of pyorrhœa. Goadby's form showed clubs, or club-like swellings. It precipitated the casein in milk, which became clear.

4. ***Nocardia indica.***—Kanthack, 1893, studying specimens of black and yellow mycetoma which came from India, concluded that the

latter variety was a true actinomycosis, and attempted to show that the former was the same, only in a degenerated condition.

He only examined the specimens microscopically, as no cultures were possible, and named the fungus in question *Oōspora indica* Kanthack, 1893, calling his two varieties *O. indica* var. *flava* and *O. indica* var. *nigra*. The name of this fungus, translated into more modern nomenclature, becomes *Nocardia indica* (Kanthack, 1893).

Boyce and Surveyor (1894) clearly proved that the melanoid variety was due to quite a different fungus from that causing the ochroid variety, which latter they considered in some, but possibly not in all, cases to be an actinomyces, a conclusion in which they were supported by Hewlett and by Boccaro. The latter analyzed one hundred cases of Madura foot, of which the vast majority were black mycetomas, while seventeen had evidence of pricks with an acacia (Babul) thorn, in several of which it was found present on examination.

Kanthack's name appears to have been overlooked, but it certainly has priority as regards the fungus of an actinomycotic nature causing the ochroid variety of mycetoma as seen in India, but difficult of recognition in that it was not cultivated.

In 1892, Gémy and Vincent described a parasitic disease of the foot in Algeria, which they considered analogous to, if not identical with, the ochroid variety of Vandyke Carter's mycetoma.

In 1894, Vincent, still working in Algeria, met with a streptothrix in a similar case. This fungus, which was first known as *Streptothrix maduræ* Vincent, 1894, is believed to be identical with the fungus found by Boyce in London in an agar tube inoculated in India from a case of the ochroid variety of mycetoma.

This streptothrix found by Boyce is, of course, an entirely different organism from the mucor-like fungus called *Chionyphe carteri* mentioned above, which therefore cannot be placed in the list of synonyms of *N. maduræ*, as has been done by some authors.

Boyce's culture showed a fungus without club-shaped extremities which grew very slowly on agar, glucose agar, and glycerine agar, at a temperature varying between 35° C. and 37° C. No formation of pigment was observed, but it was remarked that the organism closely resembled that of actinomycosis.

In 1904, Cornwall reported the cultivation of Vincent's organism in India. He washed the grains in six changes of sterile salt solution, and then planted them on agar in tubes. After an interval of one or two months a growth appeared, which in some cases assumed a pink colour and in others remained a dull white. In subcultures it grew more freely, preserving its characteristics, one of which was to adhere so closely to the medium that each nodule had to be literally dug out when it was required to transfer it to another tube. Puff-balls formed in broth and hay infusions, while it was noted that the fungus required plenty of oxygen for its growth and only occasionally formed the pink pigment.

This description by Cornwall leaves no doubt in our minds that he met with Vincent's organism in a case of the ochroid variety of mycetoma, and if this is correct, then Kanthack's name assumes its priority and Vincent's becomes a synonym, and the correct name of the fungus is *Nocardia indica* (Kanthack, 1893), and this is supported by Strong's culture of the same fungus from an Indian mycetoma in 1908.

With regard to the remaining history of the fungus, it should be noted that in 1898 Legrain, and in 1899 Brault, again described its presence in Algeria, while in 1901 Albertini and Desvernine reported its presence in Cuba, and in 1902 Brumpt discovered that it existed in Abyssinia, while Sommer y Greco demonstrated its presence in the Argentine in 1904, and Williamson in Cyprus in 1905, in which year Brumpt, in his classic on Mycetomas, stated that he had obtained it from India, Somaliland, and Senegal.

In the same year, Pelletier described a case of mycetoma with red grains which he saw in Saint Louis, in Senegal. The grains were very small, from 0·4 to 0·5 millimetre in diameter, and of a beautiful vermilion red colour. In the same year Laveran published a paper upon Pelletier's mycetoma, in which he says that it was possible on making sections of the tumour to easily discern therein little red spots of variable size which stood out from the surrounding neoplasm. These grains contained a large number of Gram-positive micrococcal-like bodies embedded in a ground substance. These bodies, which measured 0·7 micron in diameter, were never found isolated, but always in masses or short chains. No trace of a mycelium could be seen, and for this reason he gave it the name of *Micrococcus pelletieri* Laveran, 1906. But coccal-like forms are commonly found in nocardial infections, and in 1912 Thiroux and Pelletier reported that this red mycetoma was fairly common in Senegal, where one of them had met with eight cases, from one of which, a suppurating tumour of the right side of the chest, they obtained cultures on Sabouraud's medium which very much resembled those of *N. maduræ*, but differed therefrom in the following particulars:—

1. The growths were ruby red from their commencement.
2. It had only so far been grown on Sabouraud's gelatine.
3. The growths did not penetrate into the gelatine, and were easily detached.
4. In the parasitic stage the organism takes the form of a micrococcus in zooglea.

They renamed the parasite *Oöspora pelletieri*. In the discussion on this paper, Laveran agreed with Thiroux and Pelletier's finding, and Pinoy pointed out that the only real differences between it and *N. maduræ* were the greater intensity of the red colour and the more abundant sporulation. Further, he suggested that the correct name was *Nocardia pelletieri*. Under these circumstances, *N. pelletieri* would become simply a synonym of *N. indica*, of which the full list of synonyms has been given on p. 1058.

Clegg and Hobdy (1916) described *N. indica* in a native woman in Hawaii.

Nocardia indica, with yellow or red grains, possesses Gram-positive but not acid-fast hyphæ, without clubs. It forms restricted growths under aerobic surroundings at 22° C. and 37° C., but will not grow under strict anaerobic conditions. The cultures are without any distinct odour. It is usually said not to liquefy gelatine or blood serum, but Koch and Stutzer say that it has a peptonizing effect after a long time. Milk is not coagulated, but after some time is cleared. Pinkish colonies are produced on the agars and on potato. It is non-pathogenic for animals, as far as is known.

5. *N. garteni*.—Garten, 1895, met with an organism in cases of actinomycosis in man which he called *Cladothrix liquefaciens* No. 2, in order to distinguish it from Hesse's fungus, which he called *Cladothrix liquefaciens* No. 1; but Brumpt, in 1910, altered Garten's name to *Discomyces garteni*, which now becomes *Nocardia garteni* Brumpt (1910).

This fungus was grown in 1895 by Garten from the lesions of a case of necrosis of vertebræ and ribs, which was associated with abscesses, sinus formation, and empyema. The grains were composed of a tangle of ramified filaments without club formation.

The organism was an aerobe which grew easily on various media, producing on gelatine fine greyish-white points. On the fourth day liquefaction commenced, and was completed by the eighth day. Nothing is said as to the liquid being coloured in any way, and, therefore, we must assume that it was not tinted. On agar, glycerine, and glucose agar it formed a greyish-white growth, which became somewhat wrinkled on the surface after two to three days. The wrinkles are deep folds on glycerine agar.

On serum it forms a white layer, which becomes wrinkled and folded after forty-eight hours, when commencing liquefaction may be noted. On the third day the liquid has increased considerably, and by the sixth day the whole serum is reduced to a perfectly clear fluid. On potato it gives rise to white colonies, while the surrounding medium becomes greenish in colour. It apparently was not grown on eggs, milk, broth, or peptone solutions. It is pathogenic for rabbits and guinea-pigs.

6. *N. krausei*.—In 1896, Krause found an organism in an abscess of the lower jaw, in a man in Germany, which was characterized by having long and short rods and club-like forms resembling the diphtheria bacillus.

It did not grow at 22° C. nor on gelatine or potato, but it was a facultative anaerobe which formed slightly yellowish colonies on glycerine agar and was not pathogenic for rabbits, guinea-pigs, or mice.

This fungus was named *Streptothrix krausei* by Chester, 1901, which name has become changed to *Nocardia krausei* (Chester, 1901).

Allied to, or identical with, this species are the fungi causing the conditions described by Mosetig-Moorhof, Dor, and Poncet, and often called 'pseudo-actinomycosis' or the mycoses with yellow grains, which are larger than those of the ordinary actinomycosis, while they are less numerous in the pus. Microscopically they show a tangle of filaments longer and larger than those of ordinary nocardias, between which lie micrococcal-like débris. They never show clubs at the periphery, and do not grow on solid media like gelatine. They grow quickly in broth, forming a skin on the surface. Cultures on serum give clavate forms like the diphtheria bacilli.

The fungus causing the above conditions was named *Nocardia ponceti* by Verdun in 1913, and may be a synonym for *N. krausei* (Chester, 1901) for the following reasons:—

A. The pseudomycetomatous condition of Poncet does not differ from the definition of actinomycosis given at the commencement of this paper.

B. *N. ponceti* only differs from *N. krausei* in the following details:

1. *Broth is rendered turbid and has a bad odour*, but Foulerton has pointed out that this turbidity, together with the odour which was described as being associated with these growths, may have been due to the pus not being collected aseptically, and therefore the turbidity and odour may have been due to contamination, as in addition to these characters *N. ponceti* forms a typical puff-ball, just like *N. krausei*, in which the turbidity and odour are absent.
2. *According to Verdun, it does not grow on agar.* It is not known whether *N. krausei* grows on plain agar, but it can grow on glycerine agar and (according to some authors) on glucose agar.

C. They resemble each other in:—

1. Morphology.
2. They both possess clavate forms like the diphtheria bacilli.
3. Both grow on serum.
4. Neither grows on gelatine.

Other reactions are given for one, but not for both organisms, and are, therefore, useless for purposes of comparison.

We therefore, at present, see no reason why *N. ponceti* should be considered as a species distinct from the older *N. krausei*, of which its name becomes a synonym.

7. *Nocardia somaliensis.*—Bouffard observed two cases of a mycetoma at Jibouti, in French Somaliland, which appears to be peculiar both in its histological appearances and in its cultural characters. Brumpt, in 1906, classified this fungus in his new genus, *Indiella* Brumpt, 1906, calling it *I. somaliensis* and pointing out that, judging by the descriptions given by older writers in India of the macroscopical appearances of some of the ochroid varieties of

mycetoma, this variety might be found to be more common than Vincent's *N. maduræ* (=*N. indica* of Kanthack).

Balfour (1911) reported the presence of the same causal agent in a case of mycetoma of the hand in the Anglo-Egyptian Sudan, and gave a photomicrographic illustration of the growth; and in the same year Fülleborn described and gave excellent illustrations of a case from South-West Africa, which occurred in a Herero aged twenty years. A study of Fulleborn's preparation induced Brumpt to alter his generic diagnosis for the fungus which, in 1913, he classified as *Discomyces somaliensis*, which, converted into our present nomenclature, becomes *Nocardia somaliensis* (Brumpt, 1906), but he is inclined to think that it ought to form a separate genus or subgenus, for which he proposes the name *Indiellopsis* Brumpt, 1913, because it secretes around itself in the grain a hard sheath, insoluble in potash and in eau de Javelle, which no other nocardia is known to do.

In 1916 we met with this fungus in a mycetoma of the foot in Khartoum.

The grains are hard, 1 millimetre in diameter, and being of a reddish-yellow colour, resemble the eggs of fish. The fungus will not grow on hay or on dura broth, but it quickly produces a white, lichen-like, folded growth, becoming yellow on the fifth to sixth day on potato, but this growth never becomes red like that of *N. indica.*

Genus Cohnistreptothrix.- In 1891, Wolff and Israel published a beautifully illustrated account of a streptothrix, which they had isolated from two cases of actinomycosis in man— viz., from the lungs and from a retromaxillary growth. This organism was considered to differ from *N. bovis* in that it grew best anaerobically, that branching was absent, and that its injections into animals were regularly positive in their result. These three characteristics induced Kruse, in 1896, to make a new species for it under the name *Streptothrix israeli.* In 1911, for reasons presently to be set forth, Pinoy founded a new genus, *Cohnistreptothrix*, with Israel's organism as the type species, and therefore its name becomes *Cohnistreptothrix israeli* (Kruse, 1896).

It appears to us to be of importance that the reader should clearly understand the nature of the organisms included in this genus, and, therefore, we digress from our main subject in order to give a brief history.

Lachrymal concretions have been known since Césoin described them in 1670. In 1848, Gruby, examining one of these objects, found it to be composed of a fungus, which he believed to be the same as that causing favus; but Cohn, in 1875, examining another such concretion, also saw a fungus, for which he created a new genus, Streptothrix, calling the fungus in question *Streptothrix foersteri* Cohn, 1875, which may be the same organism as *S. aureus* Du Bois de Saint Sévérin, 1895, and must be closely related to *Nocardia tenuis* Castellani, 1911, which belongs to the same genus, and as its colonies on agar are 'cerebriform,' it may possibly be the same or related to *Streptothrix radiatus* and *S. cerebriformis*, both described from cases of keratitis by Namyslowski in 1909, as well as the more aerobic hyphal form of Silberschmidt's organism.

Unfortunately, a mistake was made, for Cohn was not aware that the same streptothrix had already been given by Corda, in 1839, for another and quite different fungus, which is known as *Streptothrix fusca* Corda, 1839, and which is to be found in all works of any importance on systemic mycology. Therefore, as streptothrix is not available, after many changes, the generic name has become *Cohnistreptothrix* Pinoy, 1911, and to this genus Israel's human organism belongs. It differs from Bollinger's type of fungus in growing best anaerobically, in being difficult to cultivate, and in not producing arthrospores. Other allied organisms are *Cohnistreptothrix thibiergei* (Ravaut and Pinoy, 1909), also found in actinomycosis in man; *Streptothrix spitzi* Lignières, 1903, found in cattle, and probably identical with *C. israeli*, as may be Doyen's streptothrix; while *Nocardia carougeaui* Gougerot, 1909, in juxta-articular nodules, and *Streptothrix cuniculi* Schmorl, 1891, probably also belong to this genus, as well as the streptothrix recently discovered in a liver abcess in America by Bloomfield and Bayne-Jones (1915), as we have consulted the authors upon this point, with which they are in agreement. Perhaps the bacillus described by Sawtschenko, in 1896, as the causal agent of a pseudomycetomatous condition may also belong to this genus, and it is also possible that the *Coccobacillus pseudo-actinomycosis polymorphus* Berestneff, 1898, may be the same as the chromogenic anaerobic streptothrix obtained from human pus by Neschezadimenko in 1908, and carefully described.

8. *Cohnistreptothrix israeli.*—This organism appears to be of increasing importance in human pathology, for, according to Pinoy, it appears to affect man more often than *Nocardia bovis*. It was first discovered in man, as mentioned above, by Wolff and Israel in Germany, and has since been found in thirteen cases in the United States by Wright. It has also been found in cattle by Lignières and Spitz (1904) in the Argentine, and by Pinoy (1913) in France.

It is composed of short and long rods, some of which show club-like swellings, while in old cultures spores which resemble cocci in appearance can be seen. It grows but poorly in the presence of air, but much better anaerobically at 37° C. on agar, on which it forms dew-like drops, which later become yellowish and generally remain discrete. In broth it forms a deposit of small scaly particles. It does not grow on gelatine at the room temperature of Europe, but egg cultures show typical branched filaments with club-like ends, which later break up into bacillary and coccal forms, but true arthrospores (*i.e.*, resistant spores) are not produced. It forms granulation tumours when inoculated intraperitoneally into rabbits and guinea-pigs, after an interval of four to seven weeks. In these tumours typical actinomycotic grains can be found, containing branched filaments with clavate ends.

9. *Cohnistreptothrix thibiergei.*—This fungus was discovered in 1909 by Ravaut and Pinoy in a case of actinomycosis which produced generalized subcutaneous and intramuscular nodules in a man in France.

The nodules opened and discharged blood-tinged pus, in which the fungus was seen sometimes in isolated bacillary form and sometimes as very small white grains, which in the tissues might measure some 80 microns and be composed of a radiating mycelium with or without fine club forms. It grows well aerobically and anaerobically, but the former produces more bacillary and the latter more filamentous forms. The optimum temperature is about 37° to 38° C. It does not appear to be pathogenic for laboratory animals.

Climatology.—The geographical distribution of this variety of mycetoma is as follows:—

I. *Black actinomycosis :* Only one variety of this is known—viz.:—

Babès and *Mironescu's black actinomycosis,* found in Roumania and caused by an unknown fungus.

II. *Yellow actinomycosis :* This form is well known in North America, and Sutton, of Kansas City, in 1913, in addition to drawing attention to four previously described cases, added two from his own practice. The usual microscopical appearances shown in yellow actinomycosis are depicted in Fig. 848, but the only method, known to us, of distinguishing the nine forms of actinomycosis classifiable under this heading is by cultivation, as will be indicated below. The nine varieties known to us are:-

1. *Israel's yellow actinomycosis,* found in Europe and America (North and South), and caused by *Cohnistreptothrix israeli* (Kruse, 1896).
2. *Ravaut* and *Pinoy's yellow actinomycosis,* found in France, and caused by *Cohnistreptothrix thibiergei* Ravaut and Pinoy, 1909.
3. *Acland's yellow actinomycosis,* found in Europe, but the distribution of this form requires further investigation. It is caused by *Nocardia bovis* (Harz, 1877).
4. *Bouffard's yellow actinomycosis,* found at Djibouti, in French Somaliland, in the Anglo-Egyptian Sudan, and in South-West Africa, and caused by *Nocardia somaliensis* (Brumpt, 1906).
5. *Krause's yellow actinomycosis,* found in Europe, and caused by *Nocardia krausei* (Chester, 1901).
6. *Garten's yellow actinomycosis,* found in Europe, and caused by *Nocardia garteni* (Chester, 1901).
7. *Hesse's yellow actinomycosis,* found in Europe, and caused by *Nocardia liquefaciens* (Hesse, 1892).
8. *Chalmers* and *Christopherson's yellow actinomycosis,* found in the Anglo-Egyptian Sudan, where it appears to be not uncommon, and caused by *Nocardia convoluta* Chalmers and Christopherson, 1916.
9. *Eppinger's yellow actinomycosis,* found in Europe, America (North and South), Asia, and Africa, and caused by *Nocardia asteroides* Eppinger, 1890.

III. *Red (sometimes yellowish) actinomycosis :* Only one form of which is known:

Carter's red (sometimes yellowish) actinomycosis, found in, India, Hawaii, Argentina, Cuba, Senegal, Algeria Cyprus, and Somaliland, and caused by *Nocardia indica* (Kanthack, 1893), synonym, *Streptothrix maduræ* (Vincent, 1894).

This organism has red or yellowish grains, which produce pinkish colonies on the agars (Plate VI., Fig. 8) and on potato. Kanthack's name was overlooked until recently.

Ætiology.—The fungi causing actinomycosis belong to the genera Cohnistreptothrix and Nocardia, and are best arranged by considering the different varieties of the disease, classified, like the Maduromycoses, according to the colour of the grain and the name of the discoverer.

They may be divided into:—

I. The *black actinomycosis*, with black grains.
II. The *white* or *yellow actinomycoses*, with white or yellow grains.
III. The *red* (sometimes *yellowish*) *actinomycosis*, with red (sometimes yellowish) grains.

I. THE BLACK ACTINOMYCOSIS.

Only one variety, found in Europe, is known—viz., *Babès and Mironescu's black actinomycosis*, of which the fungus has never been classified.

II. THE WHITE OR YELLOW ACTINOMYCOSES.

These may be differentiated by the characters of causal organisms into:—

A. Fungus difficult of cultivation, grows best anaerobically, arthrospores absent—Genus 1, *Cohnistreptothrix*.
  (*a*) Yellow grains:—
    1. *Israel's yellow actinomycosis*, caused by *C.* ***israeli*** Kruse, 1896.
  (*b*) Very small white grains:—
    2. *Ravaut and Pinoy's yellow actinomycosis*, caused by *C. thibiergei*.

B. Fungus grows readily aerobically and produces arthrospores—Genus 2, *Nocardia*.
  (*a*) Clubs present:
    3. *Acland's yellow actinomycosis*, caused by *N. bovis* Harz, 1817.
  (*b*) Clubs absent.
  (*c*) Hard sheath around grains:
    4. *Bouffard's yellow actinomycosis*, caused by *N. somaliensis* Brumpt, 1906.
  (*f*) Hard sheath absent.
  (*m*) No growth on gelatine.
    5. *Krause's yellow actinomycosis*, caused by *N.* ***krausei*** Chester, 1901.
  (*n*) Growth on gelatine.
  (*o*) Blood serum not liquefied:—
    6. *Eppinger's yellow actinomycosis*, caused by *N. asteroides* Eppinger, 1890.

(*p*) Blood serum liquefied.

(*w*) Pathogenic for laboratory animals:—

7. *Garten's yellow actinomycosis*, caused by *N. garteni* Brumpt, 1906.

(*x*) Non-pathogenic for laboratory animals.

(*y*) Gelatine liquefied:—

8. *Hesse's yellow actinomycosis*, caused by *N. liquefaciens* Hesse, 1892.

(*z*) Gelatine not liquefied:—

9. *Chalmers* and *Christopherson's yellow actinomycosis*, caused by *Nocardia convoluta* Chalmers and Christopherson, 1916.

III. THE RED (SOMETIMES YELLOWISH) ACTINOMYCOSIS.

There is only one known variety—viz., *Carter's red* (sometimes *yellowish*) *actinomycosis*, of which the causal organism is *Nocardia indica* (Kanthack, 1893).

The reasons for believing that these are the causal organisms of the disease are the same as for maduromycosis, and need not be repeated.

Pathology.—This is much the same as in maduromycosis.

Morbid Anatomy.—A young growth removed *in toto* can be divided into two portions, viz.:—

1. A dense matrix.
2. A number of irregularly shaped darker bodies, 'the fungal masses,' embedded in the matrix.

THE MATRIX.—When the matrix is studied by the aid of higher magnifications, it will be seen to be composed of white fibrous connective tissue containing a large number of connective-tissue corpuscles, and here and there a bloodvessel or a small group of bloodvessels which may or may not be associated with a collection of cells, and, in addition, lymph spaces and small collections of fat cells mostly associated with the bloodvessels. When these vessels are studied more carefully, some will be observed to be more or less normal, while others show signs of periarteritis or endarteritis of varying degree, which produce diminution and even occlusion of the lumen.

Connected with many of these vessels, and often more or less surrounding them, lie dense masses of cells, which when carefully studied appear to be all mononuclear. They are not all of the same category, however, for some, judging by their nuclei, appear to be derived from the endothelial cells of the vessels. Another type of cells is characterized by a darker staining nucleus, and appearing when cut in certain directions as though it possessed very little cytoplasm, but, when seen more correctly, has a relatively fair quantity of cytoplasm in proportion to the size of the nucleus. The nucleus being placed excentrically, and the cytoplasm being non-granular and not eosinophile, this cell agrees with Unna's description of a healthy *plasma cell* as seen in actinomycosis.

A third type of cell shows a large vesicular nucleus situate excentrically in a relatively large quantity of cytoplasm, which is either eosinophile or contains eosinophile granules, and corresponds exactly with Unna's description of degenerating plasma cells as seen in actinomycosis.

FUNGAL MASSES.—The darker irregular bodies seen embedded in the matrix, if examined by the aid of higher magnification, can be seen to consist of fibrous tissue and cells surrounding a portion of the fungus, and have, therefore, for purposes of distinction, been termed 'fungal masses.'

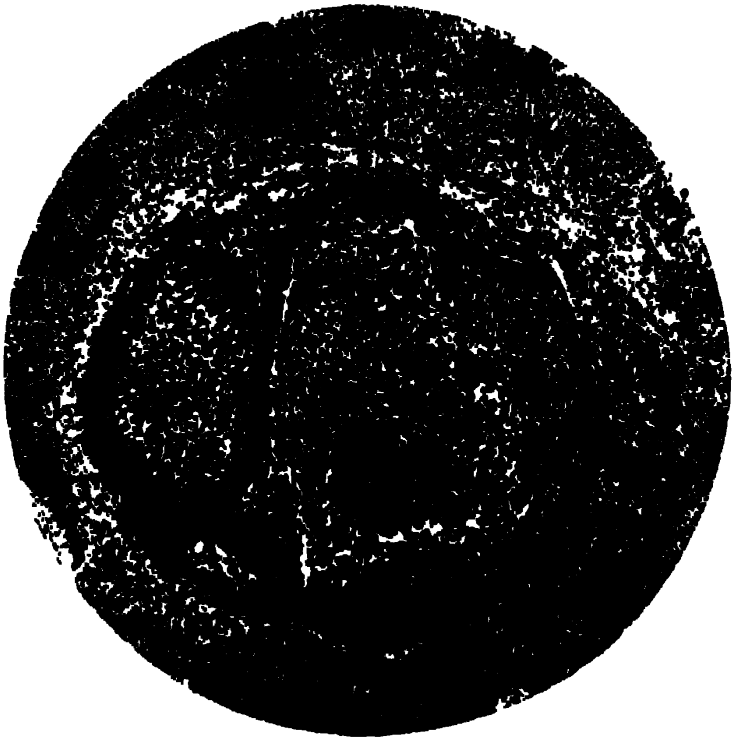


FIG. 848.—ACTINOMYCOSIS.

When a typical fungal mass is examined by means of a moderately high magnification, it can be seen to be composed of several distinct areas, which, working from the fibrous tissue matrix towards the fungus, lie in the following order:—

1. *The Fibrous Sheath.*—This is continuous with the fibrous tissue forming the matrix of the whole growth, as already described.

2. *The Fibrocellular Layers.*—Directly under the dense fibrous tissue there lies a thicker or thinner area composed of loose fibrous tissue, containing in its meshes cells and thin-walled vessels; this area may be termed the fibrocellular layers.

3. *The Cellular Sheath.*—Internal to the fibrocellular layers comes a mass of cells which may be called the cellular sheath.

4. *The Grain.*—Situate in the cellular sheath there lies a more or less distinctly or indistinctly striated body, of varying shape, and often with irregular edges, which is the grain, and is composed of the fungus and its surrounding matrix.

FIBROUS SHEATH.—When the fibrous connective tissue forming the matrix is examined, in the vicinity of a fungal mass, it will be observed to show collections of cells at intervals.

FIBROCELLULAR LAYERS.—These layers are composed of loose fibrous tissue, holding in its meshes plasma cells, healthy and degenerating polymorphonuclear cells, giant cells, and bloodvessels.

With regard to the giant cells, they may be seen to contain fungal masses, or these may be observed escaping therefrom, or the giant cells may be remarked to be separated from the fungal mass by a little distance and to be damaged, while polymorphonuclear cells lie near the fungus, and the adjacent layers of the fibrocellular tissue may be observed to be arranging themselves circularly so as to circumscribe the new fungal growth, and so to commence the formation of a new fungal mass.

When two fungal masses lie in close approximation to one another without the intervention of dense fibrous tissue, it will be observed that small areas of the fibrocellular layers adjoining the two masses show signs of granular degeneration.

Another interesting feature, but by no means confined to the fungal masses, is the presence of cells containing one or several, small or large, rounded eosinophile globules. These were called fuchsin or Russell bodies by Kanthack, and botryomycotic bodies by Archibald (1911), who published some excellent illustrations thereof in Plates XV. and XVI. of the medical volume of the Fourth Report of the Khartoum Laboratories. They are a product of the fungus, and are frequently seen in nocardial infections lying in cells at a distance from the fungus, in which case they are a great aid in diagnosis, as indicating the probable presence of a fungus somewhere. They are also seen in masses cut longitudinally and lying in lymph spaces. They have been recorded by all workers at actinomycosis and maduromycosis since the days of Kanthack, and appear to us to be probably the same material as that forming the club-like dilatation of the extremities of the hyphæ in *N. bovis* and other nocardias, and that they may possibly be a protective substance excreted by the fungus which only under certain conditions consolidates into the eosinophile form and into the clubs of certain species of nocardia.

THE CELLULAR SHEATH.—All our observations tend to support Brumpt's view that primarily the fungus is enclosed in a cell which in the younger fungal areas near the older area is always multinuclear.

Further, in the present specimen, there can be no doubt that the fungus is not destroyed by the giant cell, but, on the contrary, grows and escapes therefrom and starts life as a little fungal mass of its own, in which instance the polymorphonuclear leucocytes now

appear upon the scene, and the fibrocellular coat begins to circumscribe the cells and the fungus, while the damaged remains of the giant cell are seen retiring towards the periphery.

Later, the mononuclear cells mentioned above appear, and these **various cells,** together with detritus from the destruction of similar **cells** situate in a granular network, form the cellular sheath of the **grain,** as shown in our specimens. This description, although varying in detail, does not differ materially from a composite picture such as can be derived by a study of the writings of Carter, Acland, Kanthack, Boyce and Surveyor, Unna, Schlegel, Foulerton, Brumpt, and other authors who have studied the reaction of the body against different species of the genus Nocardia.

In more advanced cases the morbid anatomy is like that described in maduromycosis, with, of course, the difference in the grain.

Symptomatology, Diagnosis.—These are the same as for maduromycosis.

Treatment.—Vaccines have not given good results in our hands. The correct treatment is removal whenever possible, but, failing this, iodide of potash in large doses may be administered.

Prophylaxis.—This is the same as for maduromycosis.

THE PARAMYCETOMAS.

Definition.—A paramycetoma is a disease which includes all growths and granulations producing enlargement, deformity, or destruction in any part of the tissues of man which are caused by fungi of any nature whatsoever, but in which grains are either absent or so few and so small as to escape observation without prolonged search.

History.—In 1917, Chalmers and Archibald first proposed this differentiation, and followed it up in 1918 by a further communication.

Clinical Remarks.—The Paramycetomas, as already stated, cannot be recognized without microscopical assistance, because they present a varied group of clinical forms comprising chronic ulcers which may seem to be non-malignant, doubtfully malignant, or malignant, of growths which appear to be innocent or which are capable of diagnosis as doubtful carcinomata, epitheliomata, or sarcomata, or with reference to which no doubt is entertained in the mind of the surgeon attending them.

If removed in the more innocent forms or in the early stages they probably do not recur, but in the later stages of the malignant forms they do recur, but probably then as true malignant growths.

As a diagnosis cannot be made clinically, it behoves us to inquire upon what it is to be based.

Diagnosis.—The recognition of a paramycetoma is based entirely upon microscopical examination, and consists in finding one or more of the following features:—

(a) Peculiar eosinophile bodies.
(b) Fungal filaments.
(c) Minute grains.
(d) Cultures and animal experiments.
(e) Minor points.

(a) PECULIAR EOSINOPHILE BODIES.—These are single bodies enclosed in cells, or several large and apparently free bodies.

In our opinion these bodies are composed of a chemical substance, apparently formed in human tissues by several different kinds of fungi, but more particularly by the nocardias. The substance may be noted lying in a lymphatic, or in the form of these bodies in cells at a considerable distance from the site of the fungus. Hence their importance in diagnosis and the necessity on discovering them for further search in the tissues, or the patient, for a fungus.

(b) FUNGUS FILAMENTS.—The most common filament to be found in a paramycetoma is the *nocardial hypha*. These are easy of recognition to the trained eye, but are apt to be mistaken by persons not acquainted with mycology and to be recognized as bacilli, while their spores, if present, may be considered to be micrococci.

Other forms of fungi, however, may cause a paramycetoma—*e.g.*, fungi of the type of a leptothrix.

It will thus be seen that just as we divided the mycetomas into the actinomycoses and the maduromycoses, so can the paramycetomas be divided by the nature of the hyphal filaments into the paractinomycoses and paramaduromycoses.

(c) MINUTE GRAINS.—These grains are very minute in size, and very few in number, and, in our experience, are most difficult to find, and, indeed, are perhaps often absent when the case may be due entirely to hyphal filaments not collected into grains.

(d) CULTURES AND ANIMAL EXPERIMENTS.—We have been unfortunate with our attempts at cultivation and in our animal inoculations, but the success attained by the Leytons indicates that these can be done at all events with certain species of fungi. Our climatic difficulties must be remembered in connection with our failures.

(e) MINOR POINTS.—Among minor points which are worth noting are the presence of many plasma cells either in good condition or degenerated.

The condition of the vessels, which often show endarteritis or periarteritis, just as in mycetoma, is also worthy of note.

Another minor point is a peculiar glassy or vitreous macroscopical appearance, which is due to a degeneration of the tissues of a glassy nature, and must not be mistaken for hyaline degeneration.

For certain diagnosis the fungal filament should be found, but, failing this, the eosinophile body is of the utmost importance. These bodies, if associated with many plasma cells, degenerated plasma cells, and changes in the bloodvessels and glassy degeneration, are almost pathognomonic of the presence somewhere of a parasitic fungus.

The differentiation from mycetoma is not difficult, as the grain is readily found in this growth, which it certainly is not in a paramycetoma.

The differentiation from malignant growth is at the same time very easy and very difficult. Very easy because at once the specimen appears somewhat different from the typical malignant growth simulated, and very difficult because it may require prolonged search before definite evidence of the presence of a fungus is found.

Prognosis.—This depends upon the site and age of the tumour and its association with malignant characters or not. If the last feature is absent, and the growth is small and can be completely removed, the prognosis is good, otherwise it is bad. If glandular excision is performed, the presence or absence of infection is of the utmost prognostic value.

Treatment.—The only known satisfactory treatment is the early and complete removal of the growth associated with glandular excision.

THE PSEUDOMYCETOMAS.

Definition.—A pseudomycetoma resembles a mycetoma clinically in the presence of swelling, ulceration, and discharge, but differs therefrom in the absence of grains, and from a paramycetoma in the absence of eosinophile bodies.

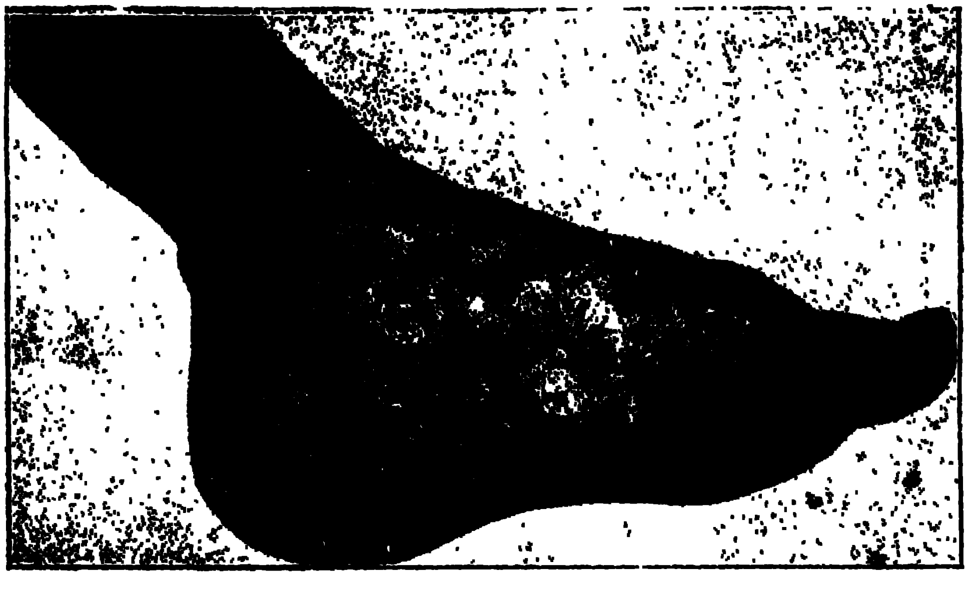

Fig. 849.—Pseudomycetoma of Frambœsial Origin.

History.—The name *pseudomycetoma* was first used by Castellani to indicate a peculiar tertiary condition of yaws, which he described as clinically somewhat resembling mycetoma. The term was adopted by us in the second edition of this work.

Remarks.—This condition is now well-known to occur in the tertiary stage of frambœsia tropica (yaws), and is not unfrequently seen in Ceylon. Breinl, in New Guinea, has described a similar condition, known to the natives by the names 'roaki,' 'buno,' or 'auma,' which he considers is a separate clinical entity from yaws. He says that the foot closely resembles Madura foot, without the presence of the typical grains in the pus.

A similar condition is known to occur in sporotrichosis. The foot in this case is swollen and painful, and shows subcutaneous and deep gumma-like swellings. Fistulæ discharging pus are also present.

A similar condition has been described by Austregesilo as being due to an angiokeratoma in the foot of a negro in Brazil. The foot was much enlarged, with several nodules, from which white material exuded. Microscopical sections enabled a correct diagnosis to be made. The whole condition, however, resembled a mycetoma, but neither grains nor fungal hyphæ could be found. His paper contains an excellent illustration.

ACTINOMYCOSIS OF THE BODY.

Remarks. The fungi producing Madura foot may occasionally invade other parts of the body instead of, or in addition to, the foot. They may attack the skin and deeper tissues of the hands, trunk, mammæ in females, and also the deep organs, lungs, heart, liver, brain. For such conditions the term 'mycetomiasis' may be used, and when the fungi found are *Nocardia bovis* and *Nocardia israeli*, the term 'actinomycosis' is generally employed. These two fungi, in fact, seldom attack the foot. Some authorities used the term 'pseudo-actinomycosis' to indicate the condition induced by *Nocardia poncelii* Verdun, 1912, *N. liquefaciens* Hesse, 1892, *N. garteni* Brumpt, 1910.

Symptomatology.- The lesions resemble, to a certain extent, those found in the foot. The condition generally begins with indolent nodules in the skin or subcutaneous tissues, the skin over them becomes tense and glossy, and finally the nodules break down, with formation of sinuses, from which a purulent liquid exudes, containing the characteristic granules, of various sizes and colour, as described in Madura foot. Occasionally the ulcerated lesions become fungoid and large, and papillomatous purplish tumours may develop. The location of the lesions varies. The type caused by *Nocardia israeli* Kruse and *N. bovis* Harz, or *true actinomycosis*, as found also fairly frequently in temperate zones, is in most cases situated on the lower region of the face and neck, especially in the tissues under the jaw. In cattle it produces the well-known condition known as wooden tongue. It is characterized by the presence of sulphur-yellow grains in the pus. Of actinomycosis, besides the cervico-facial situation, which is the commonest, the following types have been described: The parietal, attacking the walls of the thorax and abdomen, the broncho-pulmonary, the abdominal (liver, etc.); the cerebral (very rare), in addition to the rare type situated on the foot (actinomycotic mycetoma).

Prognosis.- This depends greatly on the species of fungus causing the malady. The types due to *Nocardia bovis*, *Nocardia israeli*, or true actinomycosis, answer well to a potassium iodide treatment.

Diagnosis.—This is based on the presence of indolent or nodular masses, breaking down with formation of pus, in which grains containing the fungi are found.

Treatment.— Potassium iodide in full doses (gr. xx.) three or four times a day should always be administered.

Nodular Actinomycosis of Pinoy and Ravaut.

Historical and Geographical.—This condition and its fungus were studied by Pinoy and Ravaut in France.

Ætiology.—The condition is caused by a *Cohnistreptothrix*. Only one case is known, described by Pinoy and Ravaut, and due to *C. thibiergei* Pinoy and Ravaut, 1909 (see p. 1000).

Symptomatology.—In the only case on record there were numerous subcutaneous and intramuscular gummatous nodules, which had developed very slowly; they slowly softened, some ulcerating. In the pus the fungus was found.

Treatment.—Potassium iodide is to be recommended.

Other nodular actinomycoses of nocardial origin, and characterized by the presence of abscesses, or gummata in which fungi of the genus *Nocardia* are found, have been described by Rivière and others, and very ably in England by Foulerton.

Nocardial Abscesses.

Species of the genera *Nocardia* and *Cohnistreptothrix* may, at times, give rise to abscesses in various parts of the body. One such case was described by Broughton Alcock as being due to *Nocardia asteroides* Eppinger.

TRENCH FOOT.

Remarks.—Trench foot is not a tropical disease, but as it has been considered to be of hyphomycetic origin and ætiologically related to Madura foot by Raymond and other recent observers, we propose giving a short account of the condition.

Ætiology.—There can be little doubt that damp cold plays a very important rôle in the ætiology of the disease, but there is much difference of opinion on the point whether a low temperature is the real ætiological factor or merely a predisposing cause. Many authorities hold that trench foot is a separate entity from ordinary congelation conditions. Raymond and Parisot believe that the true ætiological agents of the malady are fungi, principally *Scopulariopsis koningii* Oudemans and *Sterigmatocystis versicolor*.

According to Castellani's researches, cocci, bacilli, and various fungi of the genera *Scopulariopsis* Bainier, *Aspergillus* Micheli, *Sterigmatocystis* Cramer, *Penicillium* Link, *Monilia* Gmelin, are often found, but they are probably secondary invaders. Castellani has noted in several cases a spirochæte. Certain authorities consider the affection to be a form of avitaminosis.

Among the predisposing causes one may mention the *race*—black troops in the trenches being much more prone to develop the condition than white troops—*fatigue and mental depression, and the wearing of puttees*.

Symptomatology. In a well-marked case the whole foot is œdematous, swollen, often of a dark red colour, and painful on pressure. Bullæ may develop, and after a variable period of time a gangrenous process may set in; but this is far from being a constant feature, and can be frequently avoided if a proper treatment is carried out. There are, however, fulminating gangrenous cases. A feature of the condition which has apparently escaped the attention of most observers is the presence in many cases of a low intermittent fever, even when there is no sign whatever of gangrene.

Prognosis.—This should be always guarded, as even if symptoms of gangrene do not occur the affection may run a very long course.

Treatment.—Raymond and Parisot recommend a boracic camphorated lotion, and in mild cases camphorated oil. Castellani has used as routine treatment, with good results, the following:—Calcium lactate in 5 or 10 gr. doses is given three times a day, and the affected parts are painted once or twice daily with an ichthyol lotion (ichthyol 1 dr., aq. ad 1 oz.), and very lightly wrapped in cotton-wool. It is advisable to keep the affected foot slightly raised by means of cushions. In severe gangrenous cases a surgical treatment is necessary.

Prophylaxis.—Trenches should be kept clean, dry, and sanitary as far as conditions permit. Officers and soldiers should receive instructions to keep the feet scrupulously clean, and wear rubber boots in wet weather when possible. In our opinion, putties should never be worn.

CHAPTER XCIV

DERMATITIS VENENATA

Definition — Remarks — Historical — Climatology — Ætiology —Symptomatology — Diagnosis — Treatment — Prophylaxis — Varieties — Rhus group — Euphorbia group - - Urtica group — Tectona group—Rue group —Buffalo bean group— Little-known group— Doubtful group—References.

Definition.—The term 'dermatitis venenata' includes a number of inflammatory skin lesions caused by the irritative action of poisonous principles contained in certain plants.

Remarks.—By the above definition it will be observed that the term 'dermatitis venenata' is here used in the restricted sense of being only caused by plants, leaving the dermatitis caused by animals to be treated in the chapter dealing with the Dermatozoiases (p. 2200). Neither does the definition include *dermatitis medicamentosa*, which is due to drugs administered internally or externally, nor does it include *dermatitis factitia*, which is caused artificially—*e.g.*, beggars rubbing in *Ranunculus scleratus* Linnæus to produce sores for the purpose of inducing pity and the money usually associated therewith or recruits or soldiers utilizing various plants for purposes of malingering.

Historical.—From very ancient times it has been known that certain plants have stinging properties—*e.g.*, many species of the genus Urtica, of which *U. urens* Linnæus and *U. dioica* Linnæus are well known in Europe—but the effects of which are slight in comparison with the results produced by the species found in the East Indies—*e.g.*, *U. urentissima* Comm, *U. crenulata* Roxburgh, *U. stimulans* Linnæus, and *U. ferox* Forster. One of the earliest remarks on the subject is to be found in Kaempfer's 'Amœnitatum exoticarum,' which was published in 1712, and in which he refers to the action of lacquer varnish on the skin.

From that time onwards scattered references may be found in books on travel, on botany, materia medica, poisons, as well as in textbooks on skin diseases. Thus in 1862 Van Hasselt made some references to the subject, as did Bazin in the same year, while Piffard in 1881 made many references to plants supposed to be causal agents.

In 1887 White gathered the whole subject together in his work on 'Dermatitis Venenata,' and following this there was a leading article in the *Lancet* on the dermatitis produced by *Primula obconica*

Hance, 1880. In 1898 Blanchard made an excellent contribution with regard to *Arundo donax*, and was followed by Havard in 1899, Reynault in 1902, who detailed facts with regard to the disease as seen in Indo-China, and by Wellman in 1907, who considered the stinging plants of Angola. Then came publications by Balch (1906), Sabouraud (1908), and the Imperial Institute (1909), the last-named discussing satin-wood. After this there are the papers by Kamgiesser in 1911, Fordyce 1912, Santa Maria 1913, Whitfield 1914, and Letcher's book with the account of the buffalo bean of Rhodesia. In 1914 Hornsey gave a good account of the 'rungus poisoning' as seen in British North Borneo.

In 1916 Vadala again referred to *Arundo donax*, and in 1917 Chalmers and Pekkola gave an account of a Sudanese dermatitis venenata caused by a member of the Rutaceæ.

Climatology.—With regard to *geographical distribution*, it is a cosmopolitan complaint, being found in all parts of the world. It, however, requires further study in the tropics, and it is for this reason that we have specially brought it forward in connection with skin diseases.

Ætiology.—The causation of dermatitis venenata depends upon:—

I. The plant.
II. Personal idiosyncrasy.
III. Confirmatory test.
IV. The active principle.

I. *The Plant.*—The following list, largely compiled from White's book, but altered so as to agree with our definition of dermatitis venenata and to include tropical plants, gives those known to us to cause the complaint:-

Anacardiaceæ: *Rhus venenata* De Candolle.
Rhus toxicodendron Linnæus.
Rhus diversiloba Engler.
Rhus vernicifera De Candolle.
Semecarpus anacardium Linnæus.
Ampelidaceæ: *Cissus pruriens* Welwitsch.
Apocynaceæ: *Nerium oleander* Linnæus.
Araceæ: *Arisæma triphyllum* Schott.
Symplocarpus fœtidus Nutt.
Araliaceæ: *Aralia spinosa* Linnæus.
Artocarpaceæ: *Antiaris toxicaria* Leschenault de la Tour.
Aurantiaceæ: *Citrus vulgaris* Risso.
Berberidaceæ: *Podophyllum peltatum* Linnæus.
Bignoniaceæ: *Catalpa bignonioides* Walter.
Borraginaceæ: *Borago officinalis* Linnæus.
Cactaceæ: *Cactus grandiflorus* Linnæus.
Compositæ: *Erigeron canadense* Linnæus.
Lappa officinalis=*L. majus* Gaertner.
Leucanthemum vulgare Lambert.
Solidago odora Hooker and Arnold.

Coniferæ: *Abies excelsa* Link.
Juniperus virginiana Thünberg.
Juniperus sabina Linnæus.
Connaraceæ: *Thuija occidentalis* Linnæus.
Cnestis corniculatus Lam.
Crassulaceæ: *Sedum acre* Linnæus.
Euphorbiaceæ: *Euphorbia corollata* Linnæus.
Hura crepitans Linnæus.
Hura brasiliensis Willdenow.
Hippomane mancinella Linnæus.
Jatropha urens Linnæus.
Stillingia sylvatica Linnæus.
Leguminosæ: *Andira araroba* Aguiar.
Leucanthemum vulgare.
Mucuna pruriens De Candolle.
Stizlobium stans Kuntze.
Linaceæ: *Linum usitatissimum* Linnæus.
Loasaceæ: *Mentzelia oligosperma* Nuttall.
Mentzelia lindleyi Torrey and Gray.
Loganiaceæ: *Gelsemium sempervirens* Aiton.
Malvaceæ: *Malache hirsuta* Kuntze.
Orchidaceæ: *Cypripedium pubescens* Willdenow.
C. pubescens Salisbury.
Papaveraceæ: *Sanguinaria canadensis* Linnæus.
Phytolaccaceæ: *Phytolacca decandra* Linnæus.
Polygonaceæ: *Polygonum hydropiper* Linnæus.
Polygonum acre Hooker and Bentham.
Ranunculaceæ: *Aconitum napellus* Linnæus.
Anemone nemorosa Linnæus.
Anemone patens Linnæus.
Clematis virginica Thünberg.
Delphinium consolidum Linnæus.
Rubiaceæ: *Cephælis ipecacuanha* Richard.
Cinchona bark and quinine.
Rutaceæ: *Ailanthus glandulosa* Desfontaines.
Haplophyllum tuberculatum (Forskal, 1775).
Pilocarpus pennatifolius Engler.
Ruta graveolens Linnæus.
Scrophulariaceæ: *Verbascum thapsus* Linnæus.
Solanaceæ: *Datura stramonium* Linnæus.
Thymelaceæ: *Daphne mezereum* Linnæus.
Tropæolaceæ: *Tropæolum majus* Linnæus.
Umbelliferæ: *Thapsia garganica* Linnæus.
Laportea canadensis Gaudichaud-Beaupré.
Urticaceæ: Many species of Urtica.

This is a long list, but all its members are not natives of the tropics, in which the more important families are the Ampelidaceæ, the Anacardiaceæ, the Apocyanaceæ, the Artocarpaceæ, the Connaraceæ, the Euphorbiaceæ, the Leguminosæ, the Malvaceæ, the Rubiaceæ, the Rutaceæ, the Tropæolaceæ, and the Urticaceæ, the genera and species of which are indicated above.

II. *Personal Idiosyncrasy.*—When the poisonous principle is contained in the juice of cultivated plants, the poisoning is largely met with among gardeners, florists, and people associated with plants in some way; when, however, the poisoning is due to a principle contained in some special hairs of a plant, whether cultivated or not, it is obvious that anyone may be affected; and when it is due to principles contained in the dust from dry wood, it is also obvious that carpenters and persons who cut or saw this wood will be most liable to be affected.

With regard to the first series of cases, in our experience, there can be no doubt that some people are more liable to the affection than others, and it would appear that certain people suffering from any form of seborrhœa or allied condition, no matter how mild, are especially liable to be troubled by dermatitis venenata.

As stated in the previous editions of this book, we should not be surprised if, in the future, it will be found that certain forms of dermatitis venenata are due in reality to some parasitic micro-organisms living in the plants or woods, and which get inoculated. The fact that, for instance, satin-wood dermatitis appears several weeks after handling the satin-wood sawdust is rather in favour of there being some *contagium vivum* which requires some time to develop and multiply sufficiently to cause symptoms of disease.

III. *Confirmatory Test.*—The crucial ætiological test is to remove the patient from the district in which the plant grows, to cure his dermatitis, and then, after a lapse of time, to test him experimentally with the suspected plant, which, if the genuine causal factor, should reproduce the eruption.

IV. *Active Principle.*—Unfortunately at present hardly anything can be said upon this subject. We know that drugs like quinine can cause eruptions, and therefore we conclude that quinine is the active principle causing the eruption produced by boiling cinchona bark; but with regard to the majority of the plants, we are entirely or almost entirely ignorant of the chemical nature of the active principle.

Symptomatology.—Sometimes the symptoms consist merely of itching, with or without an erythematous blush. At other times there may be marked erythema, with œdematous swelling in the affected part, which is often the face or the hands, or both. In more severe cases a true dermatitis may be present with papules, vesicles, or pustules, with or without such general symptoms as fever and enlargement of the local lymphatic glands.

The onset is generally sudden, and the affected person may previously have been in excellent health. The termination is in quick recovery, especially if the causal agent is removed.

Diagnosis.—The case presents the ordinary appearance of an acute dermatitis, and it requires patience and acumen to trace this to its correct cause.

The characteristics of the disease are:—

1. Acute dermatitis appearing suddenly and often without apparent cause in a previously healthy person.
2. The history of the association with some plant by handling or being affected by the odour, or even of being in the neighbourhood thereof.
3. There may be history of previous similar attacks when in the vicinity of the suspected plant.
4. The rapid recovery on removal from the causal plant.
5. The return of the symptoms when again exposed to the plant.

The differential diagnosis has to be made from other forms of dermatitis, which can usually be done by the history and by finding the causal plant, but this will not help with certain forms of acarine dermatitis when the mite infests the plant.

In such a case the only possible method of diagnosis is to examine the plant and the patient carefully, so as to exclude the presence of these insects, and to reproduce the disease by means of a plant found to be quite free from mites.

Treatment.—The essential feature of the treatment is to remove the plant from the patient or the patient from the plant, whichever may be most convenient. The next point is to remove all irritating substances by copious bathing of the whole body in water, and in some cases to recleanse the affected area with alcoholic solutions. Lastly, soothing lotions such as calamine lotion should be applied to the inflamed area.

Strickler has tried in certain types the injection of minute doses of the poisonous principles extracted with absolute alcohol.

Prophylaxis.—When the patient knows that he is susceptible to the influence of a given plant, care should be taken to avoid it.

Varieties.—Dermatitis venenata may be divided into several groups as follows:—

I. *The Rhus Group.*—Plants in which the poisonous principle is contained in a clear watery fluid.
II. *The Euphorbia Group.*—Plants in which the poisonous principle is contained in a thick milky fluid.
III. *The Urtica Group.*—Plants in which the poisonous principle is contained in fluid in special hairs.
IV. *The Tectona Group.*—Plants and dried hard woods, the dust of which contains the poisonous principle.
V. *The Rue Group.*—Plants in which the poisonous principle is apparently volatile, but acts mainly when the plants are handled.
VI. *Buffalo Bean Group.*—Plants in which the causal agent is innumerable minute hairs which penetrate into the skin.
VII. *The Little-Known Group.*—This is a group containing plants which apparently cause dermatitis venenata, but about which information is very defective.
VIII. *The Doubtful Group.*—This contains plants which probably do not produce dermatitis venenata, but perhaps harbour a mite which may be the causal agent.

I. THE RHUS GROUP.

This group includes all those plants in which the poisonous principle is contained in a clear, watery juice.

The ivy or sumac belongs to the genus *Rhus* Linnæus, which is classified either as a genus belonging to the superfamily Anacardioideæ in the family Terebinthaceæ, or more simply as belonging to the family Anacardiaceæ. The genus *Rhus* includes about 120 species, growing in nearly every part of the world; but fortunately only a few are poisonous to man, and they may be distinguished, as a rule, by their inconspicuous flowers being in loose, slender clusters or panicles in the axils of the leaves, and by their greyish-white or yellowish dry fruit.

They may be arranged in two sections, according to the structure of their leaves:—

1. Leaves trifoliate.
    Rhus radicans Linnæus.
    Rhus toxicodendron Linnæus
    Rhus diversiloba Torrey and Gray.
2. Leaves pinnate.
    Rhus vernix Linnæus.
    Rhus pumila Meerburg.
    Rhus vernicifera De Candolle.
    Rhus succedanea Linnæus.

Rhus radicans Linnæus is by many authorities considered to be merely a variety of *R. toxicodendron*. It is common in the Northern United States, while the latter is more common in the Southern United States. It has ovate or lozenge-shaped leaflets, which are either entire or toothed and pointed, while *R. toxicodendron* has obtusely crenated, lobed leaves.

Rhus diversiloba is the Californian poison ivy or poison oak, with rounded, obtuse leaflets.

Rhus vernix (synonym, *R. venenata*) is the poison elder or poison sumac of the United States, and is a large shrub or small tree. It is very poisonous.

Rhus pumila Meerburg is a small erect shrub, found in the Southern United States.

Rhus succedanea Linnæus is the Japanese wau-tree, and is well known in Tonkin and in South China.

Ætiology.—The poisonous principle is an oil (*Toxicodendrol*), which occurs in all parts of the plant and at all seasons, and not toxicodendric acid, which is merely a synonym of acetic acid, as was formerly thought to be the case.

Symptomatology.—After an incubation of one to nine days, there is at first itching in the affected area, which gradually increases in intensity, and is associated with all the signs of inflammation, producing an appearance not unlike erysipelas, and sometimes going on to vesiculation. The parts most commonly affected are the eyelids, face, and neck, but it may also occur on the hands and feet. Left to itself, the eruption remains well marked for some four to five days, and then gradually subsides, serum discharges from the vesicles, and after some desquamation the affected area returns to normal after some ten to twenty days.

Treatment.—Wash the affected parts thoroughly with soap and water, and then clean with a lotion of alcohol and ether, and finally apply the ordinary lead and opium lotion or a solution of acetate of aluminium. In mild cases calamine lotion is very efficacious.

Prophylaxis.—Remove the poisonous ivy. This can only be performed by digging up the roots.

THE LACQUER POISON.—*Rhus vernicifera* De Candolle is the lacquer or varnish-tree of Japan. Lacquer poisoning has, however, been described on p. 191, and need not be repeated here.

THE PARSNIPS. In the same group with the poisonous ivies come the parsnips, of which *Pastinaca sativa* Thomas, the common parsnip, and *Heracleum lanatum* Mich (*H. giganteum* Fischer), the cow parsnip, cause symptoms analogous to those described above. The treatment is similar.

II. THE EUPHORBIA GROUP.

The Euphorbia group is placed in the non-volatile division, because, although it is definitely known that the milky juice if it touches the skin causes dermatitis, it is not so evident that any volatile principle contained therein can act at a distance, though it is possible that it does so. The subject requires further investigation.

In this group the poisonous principle is contained in a thick milky juice, the latex, which is contained in special lactiferous cells.

Hippomane mancinella Linnæus (Euphorbiaceæ), which is the celebrated manchineel-tree of the Grenadine Islands, is also found in Colombia, South America, where it is called 'Pedro Fernandes' or 'mansanillo.' It causes very severe pruriginous and painful urticaria in people who rest under its shade. According to Martinez Santa-Maria, this eruption usually disappears in about twenty-four hours, but occasionally it may last for two or three days, or even longer.

THE EUPHORBIAS.—All euphorbias possess more or less irritating juices, which, if rubbed into the skin, cause inflammation. The thick milky latex is acid, and contains a dense oil, which is very irritating. As an example of this group may be mentioned *E. pilulifera* Linnæus or *E. resinifer* Bergmann. The former is common in many parts of the tropics, and the latter occurs in North Africa.

Hura crepitans **Linnæus, of Central America and the West Indies, and** ***H. brasiliensis*****, of Brazil, possess a milky juice, said by Piffard to cause severe swelling of the face, while the latter was employed in Brazil as a treatment for leprosy.**

III. THE URTICA GROUP.

URTICA SUBGROUP.—This is characterized by containing its poisonous principle in hairs.

This group includes the nettles which belong to the genus *Urtica* Linnæus, of which *U. urens* is the common European type, while *U. ferox* Forster is found in New Zealand, and *U. pilulifera* Linnæus occurs in the Mediterranean littoral.

Laportea Gauducheau is an allied genus, of which *L. crenulata* Roxburg in Bengal, *L. stimulans* Weddel in Java, and *L. gigas* Weddel in New Holland, produce severe urticarial eruptions, associated with pain lasting for several days.

The genus *Urera* Gauducheau belongs to the same family, being found in tropical Africa and America, while the genus *Girardinia* Gauducheau is found in tropical Africa and Asia, and both contain species with markedly urticarial properties.

In all these the poisonous principle, which is said to be of the nature of an aldehyde, is contained in a special poison apparatus, which consists of secreting cells which pour their secretion into awl-shaped filaments, or hairs which are filled with an acrid, non-volatile, albuminoid, acid liquid. These hairs penetrate the skin, and the tip, being broken in the process, discharges the poison into the dermis. The poison quickly produces the well-known urticarial eruption associated with itching, tingling, and even pain.

PRIMULA SUBGROUP.—In the same group come quite a different series of plants—viz., the primulas, primroses, etc.—which belong to the family Primulaceæ. In the tribe Primuleæ there is a section called 'Sinesis,' which contains *Primula obconica* Hance, *P. sinensis* Sabine, *P. sieboldii* E. Moir, and *P. cortusoïdes* Linnæus, which possess poison glands associated with hard poisonous hairs, contact with which produces acute dermatitis, which often begins as an erythema on the face or back of the hands, and spreads quickly to other regions. Soon the erythema becomes œdematous and swollen, and vesicles may at times appear. The general aspect of the patient with the red and swollen eyelids, red and swollen face, and the similar eruption on other parts of the body, closely resembles erysipelas, and is, without doubt, one of the forms of the complaint often called 'the rose'—*i.e.*, a non-contagious erysipelas.

It must, however, be admitted that some of the recurrent eruptions described on the hands and face of persons believed to be suffering from this or ivy-poisoning are suggestive of pellagra (see p. 1700). The erythema of pellagra is, however, generally confined to areas exposed to the light, and is usually associated with some intestinal or nervous symptoms. It is, however, as well to bear in mind the possibility of pellagra in cases of dermatitis on the hands and face recurring in the spring or autumn.

The usual treatment is to apply calamine lotion, to which a little menthol or opium is added.

ORCHID SUBGROUPS.—*Cypripedium spectabile* Salisbury, of the Orchidaceæ, is also said to possess venomous hairs, while *C. pubescens* Willdenow is also known to cause a dermatitis.

Jatropha urens Linnæus, var. *stimulosa* Pohl, growing from Virginia southwards, has stinging bristles and is called '*tread softly*.'

Malache hirsuta Kuntze (Malvaceæ), called by the natives of Angola '*utiete*,' which name it shares with other stinging species of the Malvaceæ in the same locality, has been investigated by Wellman, who finds it to be armed with hairs containing a very irritating substance. Other examples in the same locality are species of the genera *Sida* and other species of *Malache*.

Cisus pruriens Welwitsch (Ampelidaceæ) is another of Wellman's stinging plants. The fruit is covered with stinging hairs. It also has an irritating juice around the seeds, which burns the throat if an attempt at mastication is made.

Cnestis corniculatus Lam. (Connaraceæ) is a vine common in Angola and called sakupolopolo. Wellman had an unpleasant experience with the hairs from a pod.

Several other species belonging to the same genus and to *Rourea* have stinging bristles on the fruit.

Stizlobium stans Kuntze and *S. pruriens* De Candolle—synonym, *Mucuna pruriens* (Leguminosæ), and called by the natives of Angola 'eyumbi'—are armed with stinging pelose hairs: *Mucuna pruriens* is the cowhage of the East and West Indies.

IV. THE TECTONA GROUP.

This group includes trees, the handsome wood of which is used for the ornamentation of saloons, and also for making furniture. The dried hard wood gives off dust, which is extremely irritating to some people, while others appear not to be affected. One attack appears to render the sufferer more liable to the complaint, and although certain authorities claim that immunity may be acquired by attacks, there appears to be considerable doubt on this point, and, in fact, the evidence points to quite the reverse being true. The best known of these dermatites was, until recently, that caused by the wood of *Tectona grandis* Linnæus, commonly called 'teak,' which gives off a dry essential oil in the dust created by sawing, and this produces a severe form of dermatitis in carpenters and joiners, which tends to become generalized, and may be of long duration, lasting sometimes for months.

The effect of the dust of 'satin-wood'—*i.e.*, the wood of *Chloroxylon swietenia* De Candolle from Ceylon and the East Indies, or the wood of *Fagara flava* (synonym, *Zanthoxylum flavum*) from the West Indies is to produce a dermatitis. These woods contain a crystalline alkaloid ('chloroxylonne,' $C_{22}H_{23}O_7N$), which has been carefully studied by Cash, who finds that twenty-two days after application for the first time it causes a dermatitis which, beginning with itching, gives rise to papules, vesicles, and oozing points on the inoculated limb, which in due course becomes brawny and pits on pressure. In a little time the swelling spreads to the eyelids and face, ears, lips, and nose, and great discomfort is experienced. In a few days a nasal catarrh and a laryngeal cough appear. This cough is of an explosive nature, as though a hair had become lodged in the throat, and although the secretion at first is slight, later it becomes more abundant. The experimental illness lasted about forty days. Another application of the active principle produced a relapse in forty minutes.

In the ordinary way the first attack is of slow development, the symptoms appearing some six weeks after the first handling of the wood, but a relapse is of rapid development.

The illness begins with the development of an acute inflammation of the skin of the hands, wrists, face, and neck, producing an appearance somewhat resembling erysipelas, but without fever or concomitant sickness. The inflamed surfaces discharge, dry, and finally desquamate. The most suitable treatment, according to Cash, is to apply the unguentum glycerinis plumbi subacetatis of the British Pharmacopoeia every four hours, to administer bromides to allay the irritation, and opium to relieve the laryngeal cough.

Other woods with similar properties are ebony (*Diospyrus ebenum* Koni), found in Ceylon and India originally, and rosewood (*Dalbergia latifolia* Roxburg), found in India.

Andira araroba Aguiar (Leguminosae), the Goa powder tree of Brazil, produces an irritating dust when the wood is cut or sawn, so that workmen have to protect their faces.

V. THE RUE GROUP.

HAPLOPHYLLUM DERMATITIS.—This has been described by Chalmers and Pekkola as occurring in the Anglo-Egyptian Sudan. It is caused by a rue named *Haplophyllum tuberculatum* (Forskal, 1775), synonym *Ruta tuberculata* (Fig. 850), which was proved to be the causal agent by producing the dermatitis in the susceptible person by bringing him experimentally into contact with the plant for a few seconds some time after he had been cured of the original attack. At the time of the experiment the person in question was staying in a place far distant from the area where the plant grew, from which it had to be fetched for purposes of the experiment. The experimental eruption (Fig. 851) appeared in about eighteen hours after rubbing the forearm for a few seconds with the leaves and flowers, which were partially dry after their long journey. The plant only affects susceptible people.

In the original attack the incubation period was thirty hours, and began as small red papules on the hands, feet, and legs, which became swollen, red, and itching, and were associated with headache and pain in the epigastric region, but no fever. The lips, lobules of the ears, and eyelids became red and swollen, and there was much itching. Later the face became swollen, the lips cracked and oozed, and the lymph glands under the jaw and in the groin enlarged. All the symptoms rapidly disappeared when he ceased to work among these plants.

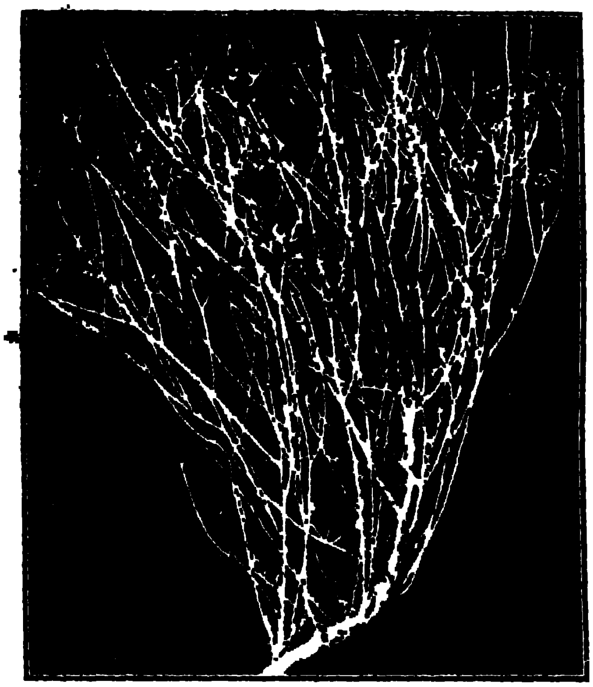

Fig. 850.—*Haplophyllum tuberculatum.*

The treatment adopted was to wash the whole body after removal from the endemic area and to apply calamine lotion.

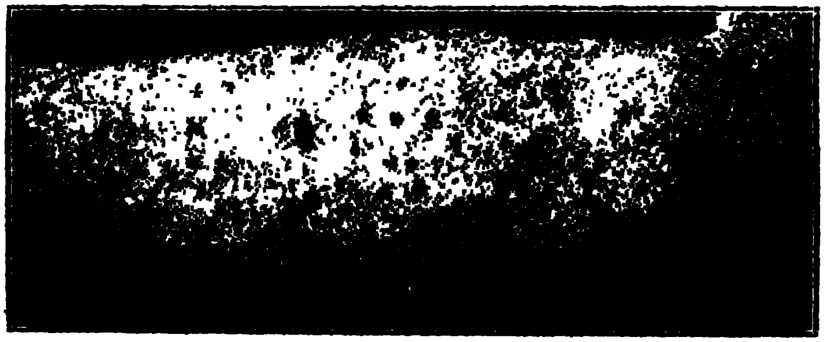

Fig. 851.—Experimental Eruption.

Other Rues.—According to Bentley and Trimen, *Ruta graveolens* causes redness, swelling, and even vesication of the skin if much handled, while Le Maout and Decaisne state that *R. montana*, found in Spain, produces erysipelatous-like conditions and ulcerating pustules on the hands of those who gather it.

VI. THE BUFFALO BEAN GROUP.

Letcher has written an interesting account of the sufferings produced by the minute hairs of the pods of the Buffalo bean. This bush, with its silky green pods, lives along the Luia River in Portuguese South Africa. The little hairs settle on the skin and set up violent irritation and burning, lasting about one hour despite remedies. Natives plaster themselves all over with mud. This laconic description by no means expresses the views of sufferers who look upon the tree as one of the ' choicest creations of the devil.'

VII. THE LITTLE-KNOWN GROUP.

This group includes dermatitis due to:—

1. Cashew nut.
2. Cinchona quinine.
3. Nasturtium.

Oleander.
Rungus.
Upas.

Semecarpus anacardium Linnæus (Anacardiaceæ), the common cashew nut of the tropics, a native of Tropical America and naturalized in Africa and Asia, is said to cause fumes when roasted which may blister the face. The mere handling of the plant does no harm.

Cinchona (Rubiaceæ) [Quinine].—Although the cinchona tree itself is harmless, yet workmen preparing quinine by boiling the bark, those who make the sulphate, and those who bottle the powder, are apt to suffer from erythema, vesicles, and pustules, which appear upon the hands, forearms, and genitalia in susceptible persons. It is believed to be due to emanations from the drug acting upon susceptible persons, who should not be longer employed at this work. The rash disappears in two to four weeks after ceasing to work with quinine.

Nasturtium.—*Tropæolum majus* Linnæus (Tropæolaceæ), which is a native of Peru, will cause a dermatitis in susceptible persons when handled.

Oleander.—*Nerium oleander* Linnæus (Apocyanaceæ), the oleander of Palestine and the East, may, in susceptible people, cause symptoms like those produced by the Rhus group, but this requires confirmation.

Rungus.—This is a curious affection, described in British North Borneo by Hornsey, and is caused by contact with any part of the tree called rungus or ringus by the natives, and said to be capable of being spread from a victim to uninfected persons. Within twenty-four hours of handling the tree itching sets in, and this is followed by a papular rash associated with fever and malaise. The rash appears first on the parts which have been in contact with the tree. The papules become vesicles and then bullæ, filled with a serous fluid, and these if secondarily infected may give rise to foul ulcers. Some people are immune. The condition heals naturally.

Upas Tree.—*Antiaris toxicaria* Lesch (Artocarpaceæ), according to Loudon, causes cutaneous eruptions when wounded, while Hasselt says that it affects the Javanese after the manner of the Rhus group when they come in contact with it. This requires confirmation.

VIII. THE DOUBTFUL GROUP.

The irritant poisoning caused by kaju-rugas, the juice of which produces painful bullæ, by kaju buta-buta, which causes violent dermatitis and conjunctivitis, have not been well studied, neither has the poisonous properties of the well-known daffodil; in fact, the whole subject requires further study.

CANE DERMATITIS.—A peculiar dermatitis is found in people handling and cutting reeds (*Arundo donax* Linnæus) in Provence, some parts of Italy, some districts of Greece, and other countries. The dermatitis was studied by Blanchard and many observers, among whom Thiebierge, Berlese, Brigi, Aravandinos, Sfameni, and Vadala, may be mentioned. It starts with severe itching and erysipelatoid eruption, associated with the formation of blebs, generally on the uncovered parts of the body, but also on the genital organs, which may become greatly œdematous, and febrile symptoms with signs of coryza may appear. After a few days the rash disappears, and is followed by desquamation.

The **Ætiology** is doubtful. Some authorities consider it to be due, to the plant itself, others to a fungus (*Ustilago hypodytes* Schlecht) and still others to a mite (*Aclerda berlesi*).

Treatment consists in applying calamine and lead lotions.

VANILLA DERMATITIS.—This is often called Vanillismus, and is due to *Vanilla planifolia*, which is a native of Eastern Mexico, but which also grows naturally in Tropical America and is cultivated in many parts of the tropics. Workmen when handling the beans suffer from itching of the hands and face, while the skin becomes covered with a pruriginous eruption and reddens, swells, and desquamates. It would, however, appear that this is not due to the plant, but to some mite thereon, as it does not occur in some works. It is said that only persons with dry skins should work with vanilla, as the least drop of perspiration or moistening of the beans causes their destruction by fungal growth. The whole matter requires further investigation.

CHAPTER XCV

ULCERATIONS

Cutaneous leishmaniasis (Oriental sore)—Muco-cutaneous leishmaniasis (Espundia)—Indian oro-pharyngeal leishmaniasis—Ulcus tropicum—Ulcus interdigitale—Ulcus infantum—Remarks on ulcers in the tropics—Granuloma inguinale—Papilloma inguinale—References.

CUTANEOUS LEISHMANIASIS (ORIENTAL SORE).

Synonyms.—Delhi boil; Aleppo boil; Biskra boil; Bagdad boil Ulcera de Bauru (Brazil); Bouton d'Orient; Ulcère d'Orient; Chancre du Sahara; Dermite Ulcereuse Circonscrite (Corre); Endemische Beulenkrankheit: Bottone d'Oriente: Godownik, *i.e.*, 'yearly boil' (Caucasus); the Tartar name is 'Il-jarassy' ('il' = year, 'jarassy' = boil); Tschiban, *i.e.*, 'yearly sore'; Dous-el-Kourmati, *i.e.*, 'date disease' (Turkish); Ghisud (Abyssinia); Habb-es-Sanawi, *i.e.*, 'yearly boil'; Habb-es-Sanah, *i.e.*, 'boil of the year'; Bess-el-Temür, *i.e.*, 'date disease' (Arabian); Salek, *i.e.*, 'annual' (Persian); Pascha-churdj, *i.e.*, 'fly-bite'; Afghan Jara *i.e.*, 'Afghan plague'; Jaman Dyscharagan, *i.e.*, 'malignant ulcer' Taschkent Jarassi, *i.e.*, 'Tashkent ulcer' (Tashkent); Mycosis Cutis Chronica (Carter); Lupus Endemicus (Lewis and Cunningham) Endemic Boil Disease (Scheube); Granuloma Endemicum (Brooke) Furunculus Orientalis (Crocker); Pian-Bois (Guiana); Sudan nodules Cutaneous leishmaniasis; Leishman nodules; Parasitic granuloma (Ferguson and Richards).

The so-called Nile boil has been demonstrated by Modder and Archibald to have nothing to do with Oriental sore, being of pyogenic origin. The so-called Bucharest boil, also, has apparently nothing to do with Oriental sore.

Definition.—A specific ulcerative affection of the skin caused by *Leishmania tropica* Wright and its varieties.

History.—The earliest account of the disease is to be found in Russell's description of Aleppo boil in 1756, in which he states that the inhabitants believed that it was caused by the drinking-water. The disease was also described by Hasselquist in 1762, Holland in 1780, Volney in 1787, Alibert in 1832, and Guillon in 1835. Tholozan, in 1866, appears to have been the first to doubt the ætiological value of the drinking-water; but Virchow is said by Hirsch to have been the first to suggest that the true cause might possibly be a parasite.

Smith in 1868 and Fleming in 1873 claimed to have found eggs of a species of *Distoma* in the sections of specimens of the tissues derived from cases of Delhi boil. Carter in 1875 described a mycelial fungus and spores. In 1880 Laveran stated that the virus of Oriental sore was probably carried by flies. Depéret and Boniet, Duclaux and Heydenreich cultivated various cocci in 1884. In 1885 Cunningham described some peculiar parasitic organisms of various size and shape, often endocellular, easily brought in evidence by staining with gentian violet. Cunningham inclined to regard these bodies as representing various stages of the development of a mycetozoal parasite, probably belonging to the group of the Monadidæ.

Riehl (1886) isolated a capsulated micrococcus. Finkelstein and Chantemesse (1887) also cultivated a micrococcus similar to the organism described by Duclaux. Poncet in the same year described a coccus in sections and a very delicate bacillus. Le Dantec and Auché in 1894 found in a case of Biskra boil a streptococcus and the *Staphylococcus albus*. In 1897 Nicolle and Nourry Bey found a streptococcus which they believed to be specific. The organism was very slightly virulent. Attempts to inoculate monkeys with the disease did not succeed. In the same year Brocq and Veillon cultivated a streptothrix from a case of Aleppo boil. Crendiropuolo isolated in numerous cases a bacillus, probably belonging to the Proteus group. Firth in 1891 stated that he had been able to confirm the presence of the Cunningham parasitic bodies in numerous cases of Delhi boil. He proposed for the parasite the name of *Sporozoon furunculosum*. In 1898 Borowsky constantly observed in twenty cases of Sarten ulcer some peculiar organisms which he thought to be protozoa. In fresh preparations the bodies were very actively motile, and presented a spherical shape; sometimes they were spindle-shaped. The maximum diameter varied from 0·5 to 3 μ. The cell-body stained very faintly. The nucleus was placed eccentrically. No chromatin bodies could be put in evidence. Schulgin in 1902 confirmed Borowsky's results, and suggested that the disease might be conveyed by mosquitoes. In 1903, in a case of tropical ulcer occurring in a boy from Armenia, Wright described bodies very similar to those found in cases of kala-azar. These bodies may possibly be identical with those seen by Cunningham in 1885. Wright's discovery has been confirmed by Mesnil, Nicolle, James, Strong, Plehn, Nattan-Larrier, Splendore, Carini, Cardamatis, Wenyon, Gabbi, Lacava, Balfour, Archibald, and others, who have greatly extended our knowledge of the disease. Marzinowsky and Bogrow state that, independently from Wright, they found similar bodies in cases of Pendjeh ulcer from Persia. In 1908 C. Nicolle and A. Sicre succeeded in cultivating the organism. In the same year and 1910 C. Nicolle and his co-workers reproduced the disease in monkeys and dogs, and in 1913 to 1914 Gonder, Row, and Laveran infected mice and other rodents. In 1917 Laveran published a most useful and complete treatise on the malady and other leishmaniases.

Geographical Distribution.—The disease is endemic in many tropical and subtropical regions. It is found also in temperate zones. In Africa it is found in Morocco, Tunis, Tripoli, Algeria, and Sahara (Biskra, Gafsa), Egypt, Sudan, Congo, West and East Africa, and South Africa; in Asia it is common in Syria and Asia Minor, in Mesopotamia, Arabia, Persia, the Caucasus, Turkestan (Tashkent), in the Turkmene district (Pendhe). It is very common in some parts of India, especially along the Valley of the Indus, in the Rajputana States, and in the North-West Provinces (Delhi, Multan, Lahore). In Europe the affection occurs in the Crimea, Cyprus, Crete, and Greece. Cases have been reported by Gabbi, Lacava, and others from Italy. It is known also in Brazil and other countries of South America, and in French and British Guiana, where it is known as Pian-bois, or forest yaws, and has been observed by Darling in Panama, so that the name 'Oriental sore' is somewhat misleading,

It is generally much more common in large towns than in the country. In some cities it is so prevalent that even visitors of a few days only may not escape it. Its occurrence appears to be influenced by the seasons, as, according to Hirsch, in the tropics it is most prevalent at the beginning of the cool season, and in more temperate climates at the end of summer. Laveran says that in Biskra, from September to October inclusive, the slightest wound tends to become transformed into the 'bouton.' In some years it has been found to be more prevalent than in others.

A peculiarity of the geographical distribution of the disease is that in the countries where it is endemic its distribution is not general, but is confined to certain districts only; hence the numerous local names given to the malady, as Aleppo boil, Bagdad boil, etc.

Ætiology.—The disease is caused by *Leishmania tropica* Wright, 1903. In the first edition of this book we expressed the belief that future investigation would show that there are several varieties of *L. tropica*, each giving rise to a slightly different clinical type of the affection, and this has come true, several species and varieties having been described, though not yet generally accepted. The description of *L. tropica* and its varieties is found in Chapter XIX., p. 378. Nicolle and Manceaux, Laveran and others have occasionally succeeded in producing in monkeys and dogs Oriental sore by inoculation of cultures. Row, by inoculating cultures of *L. donovani*, has produced cutaneous lesions in monkeys, but such lesions differ histologically from true Oriental sore.

Mesnil, Nicolle, and Remlinger have observed the parasites to be present occasionally in true polymorphonuclear leucocytes, besides being found in the mononuclear leucocytes as usual. Mesnil has observed in some cases a typical 'bacillary' form.

The medium used by Nicolle for the cultivation of the parasite is a modification of Novy-McNeal medium, and is composed as follows:—

Agar	14 grammes.
Salt	6 „
Water	900 c.c.

This is dissolved in a large flask in a Koch's stove, and then distributed in tubes. After sterilization, to each tube is added one-third rabbit-blood, collected with all aseptic precautions. The tubes are kept aslant for twelve hours, then kept at 37° C. for five days, after which they are kept at the ordinary temperature for some days before using. This medium is often referred to as the N.N.N. medium. Row has introduced a simple hæmoglobinized saline culture medium.

Histopathology.—The histopathology of the disease has been studied by Unna, Leloir, Kumm, Riehl, Wright, Strong, Bettmann and von Vasielewski, Balfour, Archibald, Darling, and others. The histological lesions in the common ulcerative variety consist essentially in the atrophy and disappearance of the epidermis of the part, and in a very extensive cellular infiltration of the corium and papillæ by various kinds of lymphoid cells, plasma cells, and numerous large roundish cells containing a single faintly stained vesicular nucleus and large amount of cytoplasm. These large roundish cells, which are probably proliferated endothelial cells, contain often many Wright's bodies closely packed together, occupying most of the available space between the nucleus and the cell periphery. Darling in his case found that the corium and papillæ were infiltrated by newly formed cells, lymphoid, endothelial, epithelioid, giant, and plasma cells. There were no necrotic areas, and a polymorphic leucocytic infiltration was not noted. Many interpapillary downgrowths were seen in the rete. The squamous epithelium was surrounded by a mass of desquamated epithelium forming the crust. The lymphatic and blood vessels in the deeper layers of the skin were surrounded by collections of lymphoid cells. Balfour, Thomson, and Archibald, noted the following principal histological features in their cases:—presence of vertical epithelial columns extending deeply downward, with a few cell-nests and isolated masses of cell infiltration. The dermis is infiltrated with cells of the large round type, polymorphonuclear leucocytes, and large numbers of eosinophiles. This cellular infiltration may extend to the sebaceous glands and hair follicles.

Communicability.—The disease may be conveyed by direct infection from person to person, by absorption of the virus through some pre-existing abraided surfaces, or small wounds or ulcers of other nature present on the skin. The reservoir of the virus would be in the affected persons and in dogs, which, as noted as long ago as 1854 by Vuillemin, may suffer from a very similar or identical affection. Certain authors have suspected geckoes and lizards to be the reservoir, but this can hardly be, as these animals cannot be experimentally infected. Camels, too, have been suspected to be a reservoir of the virus. Insects, especially flies, probably play a certain rôle in the transmission of the disease. That flies convey the disease was first claimed by Seriziat (1875) and by Tscherepkin (1876).

Tscherepkin states that by the people of Tashkent the disease is called 'pascha-churdj,' meaning 'fly-bite.' Laveran thinks that flies carry the virus on their feet and proboscis, and thus convey infection. Schulgin and others believe the disease to be conveyed by mosquitoes. Ed. Sergent and Pressat have suggested that some 'Phlebotomus' may play a rôle in the transmission of the disease, while Balfour and Thomson suggest that the bed-bug may carry the infection. Fleas and lice have also been inculpated.

The disease is inoculable from man to man, as is clearly proved by the experiments of Marzinowsky and Wenyon. It is also auto-inoculable.

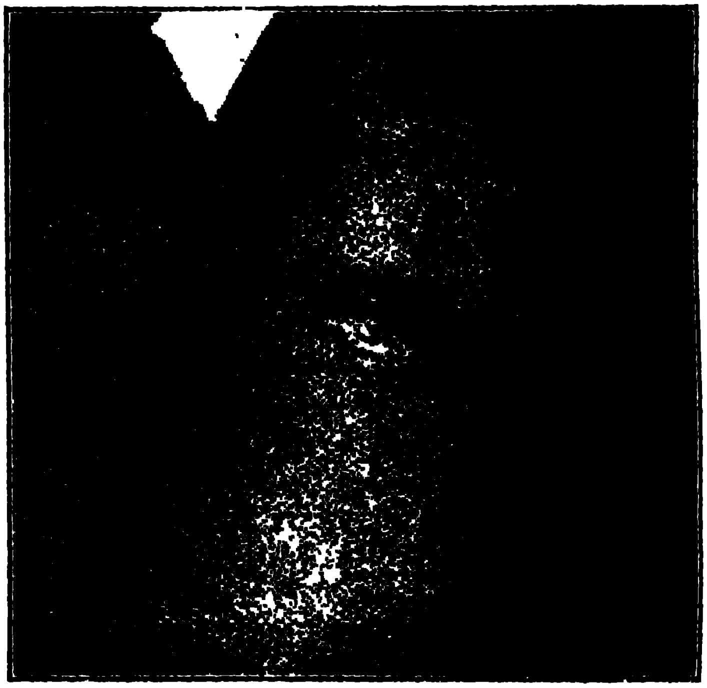

FIG. 852.—ORIENTAL SORE

Marzinowsky inoculated himself with Oriental sore by putting inside the bulla caused by an artificial burn on his hand some material (scraping) derived from an Oriental sore. After ten days from the inoculation he began to feel unwell and feverish, and suffered from headache and general debility. The fever lasted two weeks. With the beginning of these general symptoms a papule appeared at the seat of inoculation, which slowly developed into a typical Oriental sore. Scrapings contained many parasites. Wenyon has also inoculated himself, and he, too, presented fever before the skin lesion appeared. The Bagdad Jews, according to Colvilli, inoculated their children with the disease, as they thought that after having recovered once, there was no danger of getting it again.

Symptomatology.—After an incubation period varying from a few days to some weeks or several months, during which attacks of irregular fever often occur, one or several small pruriginous spots appear on the skin of uncovered parts of the body, not much dissimilar at the very beginning from mosquito-bites, for which they are often taken by the patients. The spots, however, instead of slowly fading, become red and shotty, with an inflamed areola; which later becomes markedly indurated. The papules slowly enlarge to the size of a pea or bean; the surface gradually loses its smooth and shiny appearance, and becomes covered with small thin scales. After a period of time, somewhat variable in length, but generally not exceeding three to four months, the ulceration of the nodule begins. At first the ulceration is very superficial, and exudes a yellowish secretion, which soon dries into a hard, adherent, darkish scab. Underneath the scab the ulcerative process and disintegration of the nodule continues slowly to spread. The tissues surrounding the ulcers may become œdematous. If later the darkish scab be removed, an ulcer is seen, about an inch or more in diameter, with sharp-cut, jagged edges and irregular fundus, with reddish-yellow, sometimes fungating granulations. The ulcer is generally indolent, or but slightly painful. The neighbouring lymphatic glands are not, as a rule, sensibly enlarged, unless there

Fig. 853.—Oriental Sore in a Persian Soldier.
(From a photograph of Drs. A. Bussière and Nattan-Larrier.)

is a secondary pyogenic infection. The examination of the blood taken from the finger shows often a distinct mononucleosis, and the coagulability is generally increased. The total number of leucocytes may be normal, or there may be leucopenia, or during the attacks of fever leucocytosis. In the blood taken from non-ulcerated lesions the mononucleosis is much more marked.

Healing generally sets in after six to twelve months by granulation, which begins in the centre of the ulcer, the unhealthy-looking, large, yellowish granulations giving place to healthy ones. A whitish or pinkish, often depressed and disfiguring, scar remains at the seat of the ulceration. After cicatrization, the sore may break down again.

Oriental sore may be single or multiple. Two or three are frequently found on the same patient, but occasionally there are many more, and may spread to the mucous membranes of the mouth and nose. The sores are auto-inoculable by scratching.

The seat of the ulcers is generally on uncovered parts—feet, legs, hands, arms, face. They are very seldom observed on the palms, soles, or scalp. The affection attacks people of any race, sex, and age, if they expose themselves to the infection.

Course.—The length of the incubation period is not known with certainty. It is generally stated that it varies between a few days and six weeks. Manson, however, has observed that it may be as long as five months, and Wenyon, who inoculated himself, observed that the first skin lesions appeared six and a half months after inoculation. Manson in one case made the interesting observation that the appearance of the sore was preceded several months by a fever of an irregular remittent type, not influenced by quinine, and having some features of the fever of Indian kala-azar. This fever was also noted by Marzinowsky and Wenyon, who inoculated themselves experimentally. Attacks of irregular fever during the incubation and the course have been recorded by several other authors. During one of these febrile attacks Neumann observed *Leishmania tropica* free in the liquor sanguinis of the patient.

The duration of the eruption varies from four or five months to twelve months and more. Relapses may occur, but true reinfections are rare.

Clinical Varieties.—The following clinical varieties may be distinguished:—

1. The common variety—*Oriental sore sensû stricto*—to which the description given above refers. This variety, which is the usual type met with in Asia, Africa, and South Europe, while comparatively rare in America, is characterized by the presence of one or several nodules, which slowly ulcerate, with or without symptoms of general infection, such as fever and enlargement of the spleen. Very rarely, in addition to the cutaneous nodules, there may be ulcerative lesions on the mucosa of the mouth and nose, as noted by Cardamatis in Greece and Lacava and Gabbi in Italy.

2. The *verrucose variety*, described by Ferguson and Richards,

and later by Archibald in Egypt and the Sudan, so called from the peculiar verrucose appearance of the lesions.

3. The *keloidform variety*. This is a non-ulcerative type described by Cambillet, Balfour, and Thomson, characterized by the presence of pinkish nodules, somewhat keloid-like, which never ulcerate. For this variety Balfour suggested the name 'Leishman's nodules' and Brumpt created a new species for the leishmania found in them —*L. nilotica* Brumpt, 1913.

4. The *frambœsiform variety*. This is characterized by the presence of numerous nodules capped with crusts and resembling yaws (see Fig. 854). It is fairly common in the West Indies, where it is known by the name of 'forest yaws,' 'Bosch-Yaws,' or 'Bush-Yaws.'

5. The *papillomatous variety*. This is found in South America, but very similar types seem to have been met with in North India. It is characterized by the presence of papillomatous masses, which are generally found on the lower limbs, and are designated by the Amazon natives with a word which means *sponge*. The natives believe that the same affection attacks horses, mules, and donkeys.

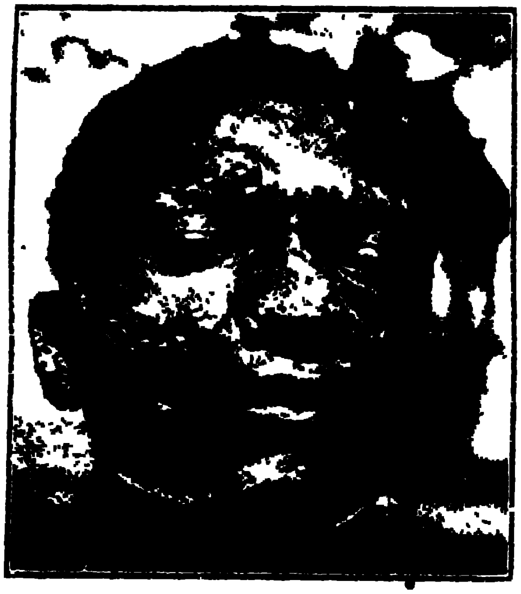

FIG. 854.—FOREST YAWS. (From a photograph by Sambon.)

This variety runs a much longer course than the common type of Oriental sore, lasting ten to fifteen years, and with very little or no tendency to spontaneous cure. It is probably due to a species of leishmania biologically different from *L. tropica*, and most authorities consider it to be due to *L. tropica* var. *americana*, the variety of leishmania which is the cause of espundia (see below).

6. The *deep ulcerative variety*. This is found in South America, and is characterized in most cases by the presence on various parts of the body of deep large ulcers running a very long course and with practically no tendency to spontaneous cure. In some cases the condition is localized to the ear, which may become perforated (*oreya de los chicleros*). One such case has recently been recorded by Low. This condition is often in reality the first stage of espundia, and is due to *L. tropica* var. *americana* (p. 380).

Diagnosis.—The diagnosis of all types of cutaneous leishmaniasis is made with absolute certainty only by examining microscopically the suspected lesions and finding the leishmanias. In numerous cases of the most common variety—*Oriental sore sensû stricto*—the diagnosis can often be made clinically, taking into account the following data:—

1. The patient comes from or is living in an affected area.

2. The few eruptive elements—often one single element—situated as a rule on uncovered parts of the body.

3. The course: a small papule which slowly enlarges into an indurated nodule, indolent, smooth, or slightly scaly, and after several months ulcerates.

4. The proximal lymphatic glands usually not enlarged.

The history, the absence usually of enlarged lymphatic glands and other symptoms of syphilis, and the uselessness of the mercurial treatment, will help in excluding syphilis. In framboesia there is a primary lesion, which, after a time, is followed by a general granulomatous eruption. We have, however, seen cases of framboesia patients who, after the general eruption has disappeared, have remained for months with a single or a few sores closely resembling the Oriental sore. In fact, we believe that in a certain number of cases it is very difficult to make the differential diagnosis between Oriental sore and ulcers of tubercular, syphilitic, or frambœtic origin: also, at times, from cancroid when the ulcer is single and situated on the face. In our experience, the only reliable way to come to a definite diagnosis in difficult cases is the microscopical examination. To do this the scab is removed, and a scraping is taken from the floor and edges of the ulcer. The preparation is then coloured with Leishman's or Giemsa's stain, or any other of the numerous modifications of Romanowsky's method, and examined for the presence of *Leishmania tropica*. The search must be prolonged in some cases, as the parasites may be very rare.

Prognosis.—In the common type the prognosis is good, *quoad vitam*. Very occasionally the disease may end fatally, owing to the ulcers becoming phagedænic, and to secondary septicæmic and pyæmic processes. In some rare cases, as observed by Cardamatis in Greece and Lacava and Gabbi in Italy, the ulcerative lesions may spread to the mucosa of the mouth. Sometimes the scars remaining after the ulcers have healed up shrink considerably, and if they are on the face, may give rise to serious disfigurement.

Treatment.—Tartar emetic is a specific. It is best given by intravenous injection, using a 1 per cent. solution in saline or simple distilled water. The solution should not be autoclaved; it should be filtered through a Berkefeld candle, or may be sterilized in flowing steam on two or three consecutive days. Five to ten c.c. of the solution are given daily for five to ten days, then every other day or twice a week until fifteen to thirty injections have been given. In children one-third or half doses are used. The intravenous injections should be given, taking all ordinary precautions and making sure that the needle is actually in the vein and that none of the liquid escapes into the surrounding tissues. Soon after the injection patients at times complain of metallic taste, giddiness, and nausea, but as a rule tolerance for the drug is easily established. Occasionally a prolonged treatment induces diarrhœa, and the patient may complain of great debility and muscular stiffness. Tachycardia has been noticed, exceptionally, and a few cases of sudden death have been ascribed to the action of the drug, which may produce a severe fatty degeneration of the heart, liver and kidneys.

Tartar Emetic Carbolic Solution.—This contains 1 per cent. tartar emetic and ½ per cent. carbolic acid, and does not need to be sterilized or passed through a Berkefeld filter.

Solutions for Intramuscular Injection.—Intramuscular injections are in certain cases very convenient, especially in children, in whom the superficial veins are often small. Unfortunately the usual solutions of tartar emetic and other antimonial salts are painful, and may induce the formation of an abscess. The following formulas will be found fairly satisfactory:—

Formula No. 1 (*Castellani*).—Tartar emetic, gr. viii.; ac. carbolici, ♏x.; glycerin., ʒiii.; aq. dest., ad ℥i.; ½ to 1 c.c. (8 to 16 minims) every other day in the gluteal region. At the time of the injection there is as a rule no pain whatever, but a few hours later in most cases there is a certain amount of pain and an infiltrated patch often develops, as after an intramuscular injection of quinine or of mercury perchloride. Care should be taken to give the injections in different spots, never giving a second one in the infiltrated part. If the pain and infiltration should be severe, hot fomentations will be found useful.

The solution is prepared in bulk in a sterile bottle, and tested for sterility forty-eight hours after preparation; it may then be put up in small 1 c.c. ampoules, which it is advisable to keep in a cool dark place. The presence of carbolic acid decreases the pain induced by tartar emetic and makes the solution sterile.

Formula No. 2 (*Castellani*).—Tartar emetic, gr. viii.; ac. carbolici, ♏x.; glycerin., ʒiii.; sodii bicarb., gr. ½; aq. dest., ad ℥i. This solution differs from No. 1 in being slightly alkaline. The results seem to be the same, and the pain induced by it appears to be about the same as with formula No. 1.

Formula No. 3 (*Martindale*).—Antimonii oxidi, gr. ⅒; glycerin., aq. dest., āā ♏xv. (for one ampoule). This preparation is good and is practically painless, but our impression is that the curative action of antimonium oxide is inferior to that of tartar emetic.

Oral Administration of Tartar Emetic.—The oral administration of the drug may be useful in conjunction with the intravenous or intramuscular injections. The following mixture is often very convenient:—

Tartar emetic, gr. v.; sodii bicarb., gr. xxx.; glycerin., ℥i.; aq. chlorof., ℥ii.; aquæ, ad ℥iii., ʒi. to ʒii. in water, three times daily, in children; double dose in adults. The presence of bicarbonate of soda and chloroform water decreases the emetic action of the drug.

Local Applications of Antimonial Preparations.—G. C. Low has used with satisfactory results a 1 per cent. antimonial ointment. A 1 per cent. antimonial lotion has been used by several authorities as a local application to the sores, and certain observers have used tartar emetic in powder, but this is extremely painful, and we do not recommend it.

Before the introduction of tartar emetic the treatment of Oriental sore was very unsatisfactory. Nitrate of mercury ointment, alum ointment, boric acid, and various antiseptics were recommended, with very poor results. Formalin often irritates the ulcer, and may produce a dermatitis. Röntgen rays have been tried, without any good results. An expectant treatment was generally advised. The scabs should be removed by boracic acid fomentation, and then the sores must be thoroughly disinfected once or twice daily with a 1 in 1,000 solution of perchloride of mercury or 2 per cent. carbolic acid, after which one of the ordinary antiseptic ointments (β-naphthol, gr. v.; vaseline, ℥i.; iodoform or europhen, gr. v.; ung. ac. borici, ℥i.; balsam. Peru., gr. v.; to vaseline, ℥i.) or an antiseptic powder (iodoform or xeroform or boric acid) is applied.

Salvarsan and atoxyl have been used without any good result.

Marzinowsky, after removing the crust and cleansing the ulcer with antiseptic lotion, applies a 10 per cent. lotion of ferropyrin to stop the bleeding, and then applies thoroughly a 50 per cent. lotion of chininum bimuriaticum daily. He says recovery takes place in between seven to eleven days.

Schulgin advises the freezing of the boil with ether. He used this method in 300 cases with good results.

Several French writers advise the use of permanganate of potassium, at first in powder form, and later as a 5 per cent. ointment.

Duncan advised placing a thin piece of lead over the ulcer, and then bandaging up.

Emily recommended the repeated applications of boric acid.

Oudiourminsky has applied to the treatment of Oriental sore Bier's stasis method, apparently with good results.

Chulguine recommended soaking the sore with a solution of methylene blue (10 per cent.).

Bussière advised dilute tincture of iodine (10 per cent.).

In other cases Bussière and Nattan-Larrier advised excision of the sore. Several physicians praise the use of silver nitrate.

Castellani had some fairly good results in two cases by washing the sores with a 5 per cent. solution of protargol, followed by the application of a 20 per cent. protargol ointment. The protargol ointment cannot be used on Europeans when the face is affected, as the protargol, after some time, induces a discoloration of the skin.

Lincoln and Aviss have obtained good results by painting the sores with a native gummy fluid, sold in native bazaars under the name of 'raurath.'

Timpeno injects 1 c.c. daily round the sore of a 1 per cent. solution of carbolic acid.

Prophylaxis.—The disease being very contagious, and being also probably spread by some blood-sucking insects, the slightest wound and any insect-bite should be thoroughly disinfected with carbolic acid 5 per cent., or tincture of iodine.

MUCO-CUTANEOUS LEISHMANIASIS (ESPUNDIA).

Synonyms.—Naso-oral Leishmaniasis, Uta, Chancre Espundique d'Escomel (Laveran and Nattan-Larrier), Leishmaniasis cancerosa (A. da Matta). Bubas Braziliana (Breda), Smith's disease, Breda's disease, Bueno de Miranda and Splendore's Leishmaniasis, American Leishmaniasis (Laveran and Nattan-Larrier).

Definition.—A chronic ulcero-granulomatous affection of the skin and mucosa of the mouth and nose due to *Leishmania tropica* Wright, 1903, var. *americana* Laveran and Nattan-Larrier, 1912.

Historical.—Espundia seems to have been present in South America since time immemorial. According to Tamayo espundia lesions are depicted on certain water vases of the ancient Incas. The malady has been known to local medical men for many years in Peru and other parts of South America, though it was often confused with framboesia and blastomycosis. Fairly good descriptions of the malady were given by Smith in 1840 and Tschudi in 1846, and later by several other observers. In 1895-1896 Breda described in a series of important publications the affection in Italy, in emigrants returning from Brazil, under the name of Bubas Braziliana, and considered it to be due to a bacillus the presence of which was confirmed by Fiocca, who claimed to have reproduced the disease in the lower animals by inoculating pure cultures of the organism. Breda's work was confirmed by Verrotti and De Amicis. The term 'boubas,' used by Breda, was a rather unfortunate one, as it led to much confusion, this term being generally used by tropical authors as a synonym for framboesia, while the natives, as noted by Splendore and others, use it indiscriminately to indicate various ulcerative lesions of widely different nature.

Escomel in 1911 gave a very good description of espundia as found in Peru. Further investigation has shown that the condition found in Brazil is identical with that found in Peru.

Bueno de Miranda and Splendore first found leishmania bodies in the ulcerative lesions, Splendore making a very complete pathological and clinical investigation of the condition, and succeeding in experimentally inoculating it in monkeys. Splendore called attention to the fact that in cultures the flagellum of the *Leishmania* found was generally longer than in *L. tropica*; he observed also that with Giemsa's reagent the parasite stained usually deeper than *L. tropica*. Laveran and Nattan-Larrier have made an important study of the parasite in tissues sent to them by Escomel, and noting the very frequent peculiarity of the nucleus being flattened, have created a new variety: *L. tropica* Wright, 1903, var. *americana* Laveran and Nattan-Larrier, 1912. Vianna had previously created a new species, *L. brasiliensis*, but this species has not been generally accepted. More recent important researches have been carried out by Horta, Carini, Lindenberg, Rabelo, Morales, Darling, Velez, Araujo, Chagas, Alfr. da Matta, Aragao, Strong, Tyzzer, Brues, Sellards, Gastiaburú, Flu, Migone, Torres, Christopherson, and many others.

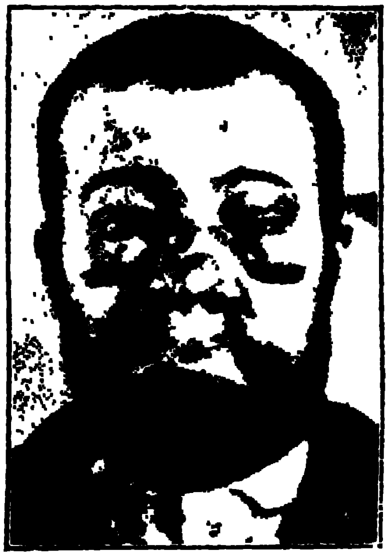

FIG. 855.—ESPUNDIA.
(After Splendore.)

Geographical Distribution.—The disease has been reported from Peru, Brazil, Paraguay, Argentina, Colombia, and other parts of South America. In Brazil it is especially common in the regions between the State of St. Paulo and the State of Matto Grosso, near the River Tiété; in Peru it is found in the regions of Caralaya and Sandia, and close to the River Madre de Dios. Cases have been reported from Panama and Mexico. It has been found in the Anglo-Egyptian Sudan by Christopherson.

Ætiology.—The disease is due to *Leishmania tropica* Wright, 1903, var. *americana* Laveran and Nattan-Larrier, 1912, which Vianna considers to be a separate species, *L. brasiliensis* Vianna, 1911 (see pp. 378, 379, and 380).

Morbid Anatomy and Histopathology.—Escomel, in a chronic case which died of cachexia, found the body extremely emaciated, and the espundial lesions extending from the oral cavity to the pharynx, larynx, and trachea. The œsophagus was also affected. The organs presented amyloid degeneration.

The histopathology of the disease has been well investigated by Breda, Escomel, De Amicis, Verrotti, Splendore, Carini, and recently very completely by Laveran and Nattan-Larrier. The lesions do not show any characteristic histological feature, the epithelial strata have disappeared, and are substituted by a fibro-leucocytic membrane; there is a large amount of granulation tissue, with numerous mononuclear leucocytes and plasma cells; a few macrophages may be seen.

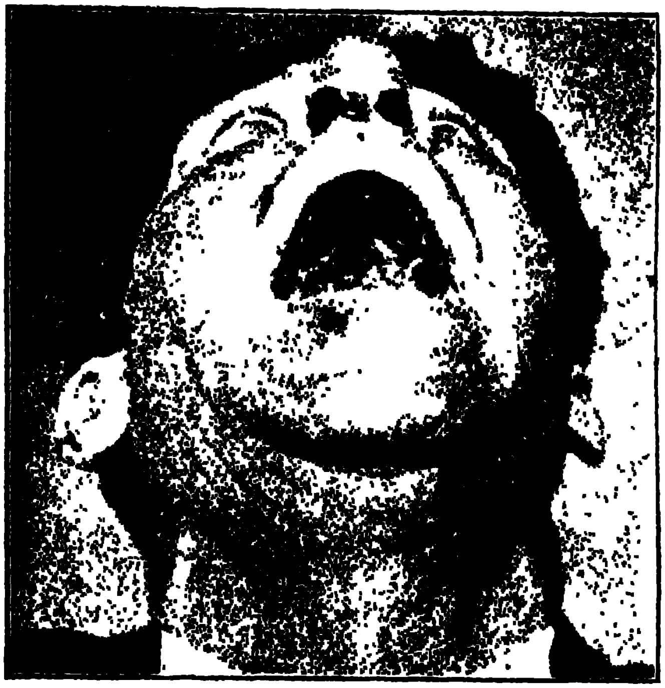

FIG. 856.—ESPUNDIA.
(After Splendore.)

Splendore has occasionally seen giant cells; no cell nests have been observed. The stroma consists of some fibrils, which are stained with difficulty. The lesions are not very vascular.

Communicability.—The infection may be conveyed by direct contact from person to person, the virus being absorbed through some abraded surface, fissure, or small wound. It may also be transmitted probably by some blood-sucking insect, most patients stating that the first lesion appeared at the place where they had been bitten by some insect. Mosquitoes, sand-flies, certain ticks and certain flies (especially tabanid) have been inculpated.

As regards the *reservoir* of the virus, certain observers suspect dogs, in which occasionally a similar or identical affection to the human one may be found. In Paraguay there is a popular belief that the rattle-snakes are the reservoir of the virus.

Darling and Townsend have brought forward the hypothesis that the

leishmania is an adaptation to man of insect flagellates. In this connection one may quote the interesting observations made by Fantham and Porter, Laveran and Franchini, (who have succeeded in infecting mammalia with certain flagellates found in fleas and mosquitoes (see p. 363).

Symptomatology.—The incubation period is unknown. The malady generally begins with a nodule on some uncovered part of the body, which fairly quickly breaks down, and an ulcer is formed. This first lesion is called by Escomel 'espundial chancre.' It is mostly found on the forearms, legs, chest, trunk, or more rarely on the face. The ulcer is generally atonic, roundish; there is very little or no pain, the fundus is granulating, and there is abundant purulent secretion which dries up, forming thick crusts. The ulcer after some months, or even one or two years, heals up, leaving a thick scar. While this primary ulcer is still open, but oftener after it has healed, the characteristic lesions occur on the mucosa of the mouth and nose, with or without the appearance of further ulcerative lesions on the skin of various regions of the body. The lesions on the mucosa of the mouth are ulcero-granulomatous, often frambœsiform, and may invade the hard and soft palate, the gums, the labial mucosa; they may form on the palate a diffuse granulomatous mass, with deep furrows. The mucosa of the nose is very often attacked, and destruction of the cartilages may take place, inducing a marked deformation of the nose. Alfr. da Matta has noted that the bones are not destroyed; the skin is often œdematous, and patches of hard œdema may be found below the eyes. The pathological process may extend to the pharynx and larynx. In some cases the patient may become aphonous, and complains of great pain during deglutition; his breath may be very offensive. There may be serotine fever.

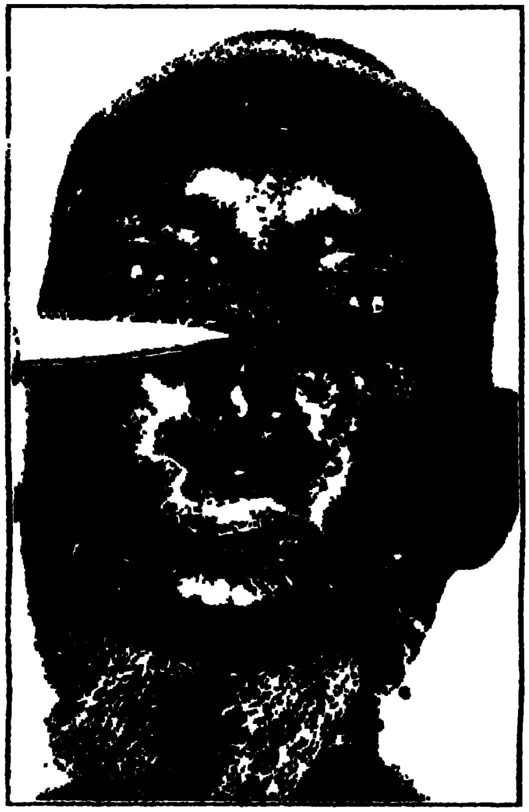

Fig 857.—Espundia A Sudan Case.
(From a photograph by Christopherson.)

The course is chronic; the disease may last for twenty to thirty years, death being generally due to some intercurrent disease. In a few cases the affection may attack mucosæ other than the naso-oral, and pharyngeal. For instance, a case of vaginal leishmaniasis has been recorded by Alfr. da Matta. In the last stage the patient becomes cachectic, and his appearance may be that of a carcinomatous patient.

Prognosis.—Before the introduction of tartar emetic by Vianna the prognosis used to be very bad, though occasionally when the diagnosis was made as soon as the primary cutaneous lesion appeared, and this was destroyed, the further progress of the disease was prevented.

Diagnosis.—The disease is distinguished from the usual type of dermal leishmaniasis (Oriental sore) by its very long course. Moreover, the latter invades the oral mucosa only exceptionally, though cases have been reported by Cardamatis in Greece, and Lacava and Gabbi in Italy. From blastomycosis it is distinguished by the presence of a leishmania, and absence of yeast-like or monilia-like fungi. From syphilis it can be diagnosed by the uselessness of the mercurial and salvarsan treatment; from morva by the absence of *B. mallei* Löffler and Schütz; moreover, morva is very rare or absent in those regions where espundia occurs. The condition is distinguishable from tuberculosis by the different histological lesions; from framboesia by the absence of the framboesiform eruption on the body, by the absence of the *Treponema pertenue* Castellani, and by the uselessness of the salvarsan treatment.

Treatment.—Tartar emetic, first used in the disease by Vianna, is a specific. The usual 1 per cent. solution in saline or distilled water, filtered through a Berkefeld candle, or sterilized in flowing steam, is given by intravenous injection (5 to 10 c.c. per injection) for several periods of five days each until twenty or thirty injections have been given. The same solution may be used as a local application to the sores, for syringing the nose, etc.

Strong solutions or tartar emetic in powder form should not be used, as they give rise to severe pain.

Mild antiseptic mouth-washes such as diluted glycothymolin and listerin or potassium permanganate (1 in 5,000) should be freely used.

According to Escomel, if the primary lesion be excised or destroyed, the further course of the disease is prevented.

Prophylaxis.—Abrasions, fissures, and any ordinary traumatic small sores, should be kept well disinfected and protected with antiseptic dressings, to prevent infection with the espundia virus. Any insect bite should immediately be touched with tincture of iodine.

INDIAN ORO-PHARYNGEAL LEISHMANIASIS.

Remarks.—It may be of interest to give a brief account of an ulcerative condition of the throat observed by one of us in two Europeans who had long been living in India.

Ætiology.—In one of the two cases observed, scrapings from the ulcers contained typical leishmania bodies very similar or identical to *Leishmania tropica* and *L. donovani*. In the other—which was the first case seen, and clinically identical to the second—no leishmania was found, but the patient had to go back to India, and no repeated examinations could be carried out. We are inclined to think that it was of the same nature. The condition may have been kala-azar, with ulcerations on the throat, though this manifestation of kala-azar has never been described; moreover, the general health was not so affected as in kala-azar of long standing. It was not Oriental sore with complications on the oral mucosa, as the skin had never been affected; moreover, Oriental sore does not run such a long course. It was not espundia, as there were no cutaneous lesions and the ulcers were not frambœsiform.

Symptomatology.—In the case in which leishmania bodies were found there was no history of syphilis or of any ulcerative lesion on the skin. He had been residing for a long time in India, and when he consulted one of us at Colombo, was going on a long holiday. He was a tall, rather stout man (European) of thirty-eight years of age, in apparently good general health, but he complained of intractable ulcers on the pharynx and soft palate, which, according to him, had been present for the last nine years, and which gave a certain amount of discomfort, though they were not very painful. No enlarged lymphatic glands could be detected. The local examination showed the presence of several ulcers on the posterior wall of the pharynx and on the soft palate; they were of various sizes, but not very large, mostly ½ to ¾ centimetre in diameter; they were roundish, and some of them not very deep. Some were covered by débris: none had a frambœsiform appearance. The patient had been treated in various ways, including a very energetic antisyphilitic treatment, without any effect. The microscopical examination of scrapings from the lesions showed leishmania bodies, apparently very similar or identical to *Leishmania donovani*. On inquiry the fact was elicited that the patient had been occasionally suffering from attacks of fever, believed to be malaria, for the last five years. The physical examination of the patient revealed nothing abnormal, but the spleen on percussion appeared to be slightly enlarged, and on deep inspiration was just palpable.

In a clinically identical condition seen in a previous patient no leishmania was found in the ulcers, but no repeated examinations could be carried out; he admitted having had many attacks of what he called 'malarial fever.' In that case the spleen was much enlarged, though the examination of the blood revealed absence of malarial parasites and pigment.

Prognosis.—The local ulcers were most intractable. The general health did not seem, however, to be very markedly affected.

Diagnosis.—This is based on the microscopical examination. Care should be taken to make a deep scraping of the ulcer.

Treatment.—This should be the same as for espundia.

ULCUS TROPICUM.

Synonyms.—Yemen ulcer, Aden ulcer, Annam ulceration, Cochin sore, Mozambique sore, Sarnes (Congo). *French :* Ulcère Phagédénique des Pays Chauds. Ulcère Phagédénique Endémique. *Italian :* Ulcera Tropicale, Phagedæna Tropica. *German :* Tropische Phagedenismus.

Definition.—Ulcus tropicum is a tropical chronic sloughing ulcer, which may take a phagedænic character, and spread down to the muscles and bones, and which, left to itself, shows hardly any tendency to heal.

History.—Phagedænic ulceration is mentioned in many of the early works on tropical medicine. Thus, Hunter in 1792 refers to it in Jamaica in the following terms:—

'Sores . . . spread quickly, and form large ulcerated surfaces. . . . The granulations turn flaccid, and even mortify in parts. The portion skinned over ulcerates afresh, and the sore becomes larger than ever. Ulcers of some standing . . . could not be healed in that country. . . . Opportunity was taken to send home men with ulcers.'

After this date there are numerous references to the complaint, which is generally described under the name of the locality in which it was found, which accounts for many of the above synonyms. In 1862, Rochard took a broader view of the disease, and in 1864 Le Roy de Méricourt introduced the term 'Phagedænic ulcer of warm countries.'

In 1874, Treille suggested that the disease was likely to prove to be of a parasitic origin, but he failed to demonstrate any parasite. Bacteria have since been described by many observers, and more recently spirochætes have been considered to be the cause of the disease, as will be described in the section on Ætiology.

Climatology.—Ulcus tropicum is found in all tropical and subtropical regions of Africa, Asia, and America. There are localities, however, such as the hinterland of Aden, the low, marshy plains of Cochin China and Tonkin, and some islands of the Red Sea, where the affection is particularly common. It may be found also, though rarely, in temperate zones, cases having been reported from Greece, Macedonia, and South Italy.

Ætiology.—Numerous bacteria have been described by Petit, Boniet, Blaise, Crendiropoulo, as being the cause of the disease. Le Dantec described in the lesions the fusiform bacillus, and considered it to be the cause of the affection. Vincent found in addition to the fusiform bacillus numerous spirochætes, and considered that the affection was due to the association of the two germs. Vincent's observations have been confirmed by Smith and Peil in Sierra Leone, Patton in Aden, and many other observers in various parts of the tropics. Prowazek has fully described the spirochæte which he named *Spirochæta schaudinni* Prowazek, 1907. This term, however, is a synonym for *S. vincenti* Blanchard, 1906.

The important researches of Keysselitz and Mayer, and the more recent ones of Wolbach and Todd, confirm Prowazek's work.

Spiroschaudinnia vincenti Blanchard, 1906 (synonym, *Spiroschaudinnia schaudinni* Prowazek, 1907).—This is a spiral-shaped organism, very actively motile, its length varying between 10 μ and 22 μ, though much shorter or longer individuals may be met with. The coils are few in number, and elongated. The organism possesses a well-marked undulating membrane, which is best brought into evidence by using Löffler's flagellar stain. A delicate, rather short flagellum is occasionally seen at one of the extremities. Forms undergoing longitudinal division are frequently observed. Prowazek distinguishes, also, male and female forms. Variously shaped regressive and rest forms may be seen. According to Prowazek, *Spiroschaudinnia vincenti*, apart from being more slender, has the greatest resemblance to the spirochæte which Prowazek himself and Hofman have described in a form of balanoposthitis.

The *S. vincenti* is often found mixed with other types of spirochætes, some slender, some thick.

According to Le Dantec, Brault, Vincent, and others, ulcus tropicum is identical with the so-called 'hospital phagedæna' which used to rage in hospitals of all countries before the antiseptic era. In our opinion ulcus tropicum is a separate disease, though occasionally, owing to secondary infections, it may take phagedænic characters similar to those found in hospital gangrene.

Inoculation Experiments—Communicability.—Experiments to inoculate the disease in men and in the lower animals have been made by several authors. Blaise inoculated himself with the secretion of a case of ulcus tropicum, but no ulcer was produced—only a slight superficial, purulent lesion, probably due to pyogenic cocci present as secondary infectious agents in the secretion which had been used for the inoculation. Blaise tried to inoculate the disease, also, in guinea-pigs, but without any definite result. Similar experiments on the lower animals by Jourdeuil and Gayer failed. Halberstädter tried to reproduce the affection in monkeys (orang-outang and *Macacus cynomolgus*), but without success.

It would seem, therefore, that, to a certain extent, the disease is not directly contagious. It is probable that some insects or other blood-sucking vermin may play an important rôle in the transmission of the disease. In Ceylon, patients often state that the ulcer developed at the site of a leech-bite. Leeches are extremely common in Ceylon and other tropical countries. Prowazek in Java has examined many leeches, but he never found any spirochætes except once. The spirochæte observed, however, was quite different from *Spiroschaudinnia vincenti*. Prowazek examined, also, on many occasions the mud of rice-fields, but of spirochætes he found only *S. plicatilis*, and once a very thin, short, very actively mobile spirochæte.

Predisposing Causes.—A hot, damp climate is said to have a predisposing influence, as cases of ulcus tropicum occur more frequently in the hot rainy season and marshy lowland localities rather than in dry or higher regions. It may be that it is in hot, marshy places that the carriers of the infection thrive.

The disease is very common among the poorer classes of the population, who go barefooted and wear but scanty clothes. We have observed it very often in beggars and in scabies patients. The disease is much more common in adults than in children, in men than in women.

Histopathology.—This has been thoroughly studied by Keysselitz and Mayer, and by Wolbach and Todd. The surface of the ulcer is covered often by a tenacious membrane composed almost solely of coarse-meshed hyaline fibrin, with detritus and masses of spirochætes and various bacteria. The fundus and walls consist of granulation tissue, which does not present any characteristic feature. The deeper tissues and corium surrounding the ulcer present a heavy lymphoid and plasma cell infiltration, and, as noted by Wolbach and Todd, numerous eosinophiles are found in the vicinity of small vessels. On microscopical examination of vertical sections of the ulcer, it will be seen that the superficial layers of the fundus show a large amount of granular detritus and numerous foci of leucocytic infiltration, while the

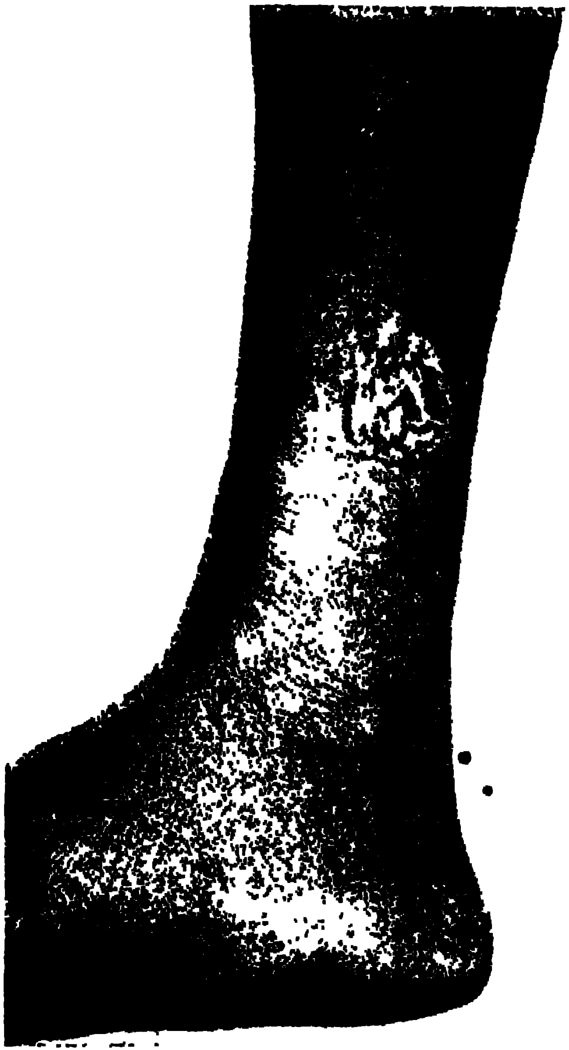

FIG. 858.—ULCUS TROPICUM: TYPICAL.

deeper layers consist of fairly dense fibrous tissue. Hæmorrhagic foci are to be seen in various parts, and, as observed by Keysselitz and Mayer, fusiform bacilli and spirochætes are found in the superficial layers, while in the deeper strata only spirochætes are present.

Symptomatology.—The affection is generally found on the lower limbs, especially the lower third of the leg, the ankle and dorsum of the foot. Occasionally it may develop on other uncovered parts of the body. It is single in most cases, but two or more ulcers may be found in some patients.

Ulcus tropicum begins with the appearance of a small, painful occasionally pruriginous papule or papulo-pustule, surrounded by a deeply infiltrated dusky red areola. The initial lesion soon undergoes purulent and degenerative changes, which rapidly extend to the infiltrated area. A sloughing process sets in, and an ulcer is formed, which gradually extends in depth and surface. The margins are not sensibly raised, nor thickened, unless the case be very old. They are not perpendicularly cut, nor undermined, as a rule, the whole ulceration having generally a roundish or oval outline, and, when the secretion is removed, a concave fundus. The parts surrounding the ulcers are often œdematous, and somewhat painful on pressure. It is remarkable, however, how comparatively little pain there is in many cases.

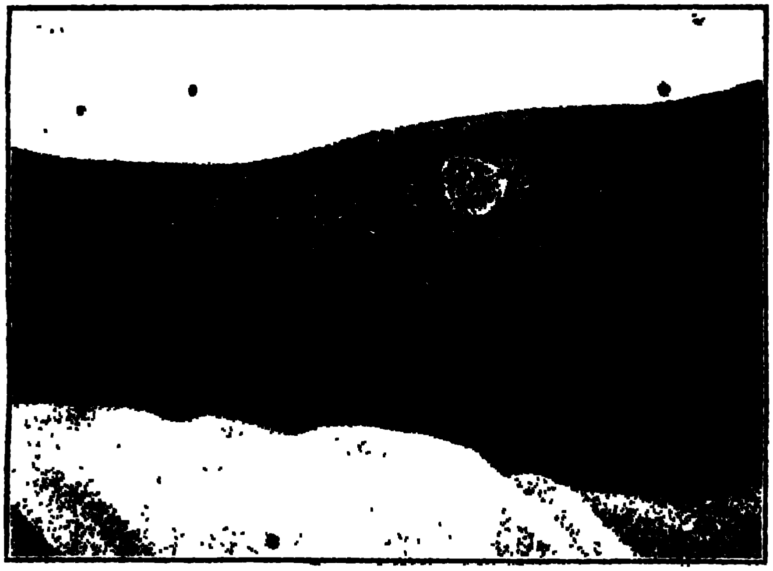

FIG. 859.—ULCUS TROPICUM: EARLY STAGE.

When the patients are first seen, the whole ulcer is generally covered with a thickish, dirty greyish secretion, exhaling a highly offensive odour. On removing the secretion the fundus will be found to be of a red colour, or in chronic cases pale pinkish, and feebly granulating.

The fundus is often somewhat infundibular in its central area, and not rarely may present a circular raised ridge, which divides the ulcer into two portions—an external more superficial one, and an internal infundibuliform one.

Occasionally, if left untreated, the ulcer may take a real phagedænic character, involving a large surface, and deepening till the deeper structures—muscles, tendons, and periosteum—are affected.

The course is always chronic, lasting for months—in fact, the ulcer has hardly any tendency to spontaneous healing if untreated. Healing takes place by a very slow process of granulation, and begins from the periphery. A thick, whitish, often disfiguring scar is left at the place of the ulcerations. At times, however, the cicatrix is at first very delicate, and the ulcer may break out again after the least irritation or traumatism.

The microscopical examination of the greyish, bad-smelling secretion shows leucocytes undergoing various degenerations, some red-blood cells, threads of connective tissue, and very often spirochætes and fusiform bacteria of various types, sometimes accompanied by the usual pyogenic cocci. In old untreated cases larvæ of flies may be found, small acarids, and ants.

Diagnosis.—According to Le Dantec, Vincent, and several other observers, ulcus tropicum is identical with 'hospital phagedæna.' The fact, however, that, in contrast to 'hospital phagedæna,' ulcus tropicum shows very little or no direct contagiousness, and in most cases is self-limited, clearly shows, in our opinion, that the two are separate diseases.

FIG. 800.—ULCUS TROPICUM.

Differential Diagnosis—*Frambœsia.*—The lesions in frambœsia are generally multiple—either granulomatous or ulcerative. Scrapings from frambœsia lesions—after the superficial strata have been removed—will often reveal the *Treponema pertenue* Castellani, which is much more slender than any of the spirochætes found in ulcus tropicum. Occasionally an ulcerative frambœsia lesion may become infected with the virus of ulcus tropicum. In our experience, however, the reverse is much more common—viz., an ulcus tropicum becomes infected with frambœsia virus, takes a papillomatous appearance, and is followed by a general eruption of frambœsia granulomata.

Syphilis.—Ulcus tropicum does not show usually the clean-cut margins and the punched-out circular or reniform appearance, with the frequent wash-leather slough on the surface, of a tertiary ulcer. The mercury and potassium iodide treatment has no influence on it.

Oriental Sore.—An old-standing Oriental sore may present some characters of a chronic ulcus tropicum, though generally a tropical ulcer is much larger. The process of ulceration and breaking down is very slow in Oriental sore, while it is very rapid in ulcus tropicum. In difficult cases the search for *Leishmania tropica*, which is present in Oriental sore, will clear the diagnosis.

Ulcus Cruris Varicosum.—There are often varicose veins visible, the parts surrounding the ulcer are congested and frequently eczematous, the ulcer is often shallow and irregular.

Ulcers of Tubercular Origin.—They are rare on the lower extremities, and their development is long and insidious. In ulcus tropicum the tubercular cuti and ophthalmic reactions are negative unless the ulcer develops in a tubercular patient.

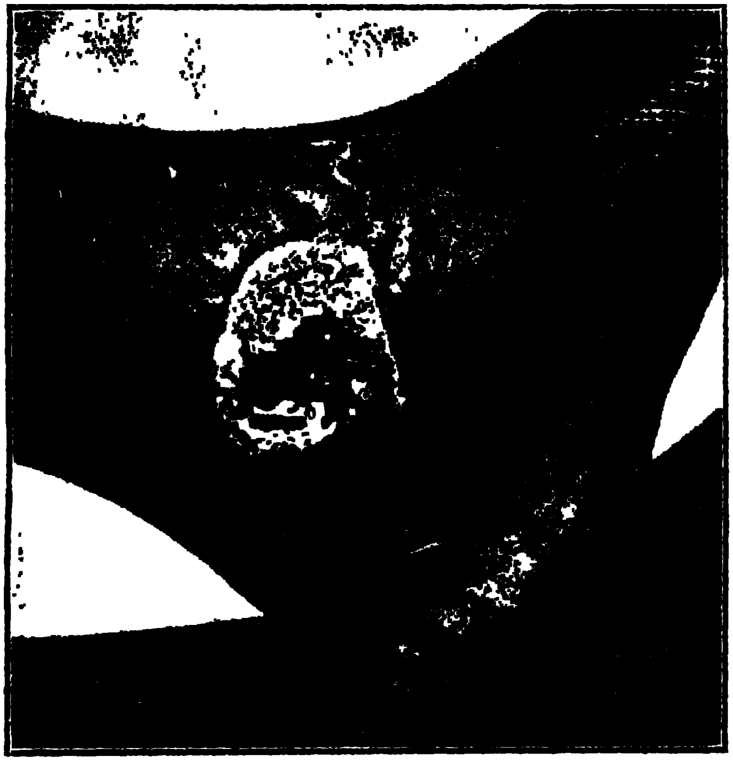

FIG. 861.—ULCUS TROPICUM.

Blastomycosis—Sporotrichosis.—In blastomycosis there are generally warty patches with minute abscesses; while the lesions of sporotrichosis often show at first the characters of gummata. The bacteriological examination will reveal the presence of the fungi.

Acladiosis.—The ulcerative lesions are multiple and of smaller dimensions. The bacteriological examination will reveal the presence of *Acladium castellanii* Pinoy.

Mycosis Fungoides.—Is generally preceded by a general pruriginous dermatitis of various character, lichen-planus-like, psoriasis-like, eczematous-like. The ulcerative lesions are multiple, and have the characters of granulomata.

Prognosis.—If untreated, tropical ulcer has very little or no tendency to spontaneous recovery, and in some cases may extend, damaging the deeper structures, tendons, muscles, nerves, and vessels. Occasionally a general septicæmia and pyæmia may supervene. In countries where frambœsia is endemic the ulcer often gets infected with its virus, and the patient develops a general eruption of frambœsia.

Treatment.—Salvarsan, neosalvarsan, and their substitutes have been administered by intravenous or intramuscular injection by Werner, Hillenberger, and others, with success in certain cases.

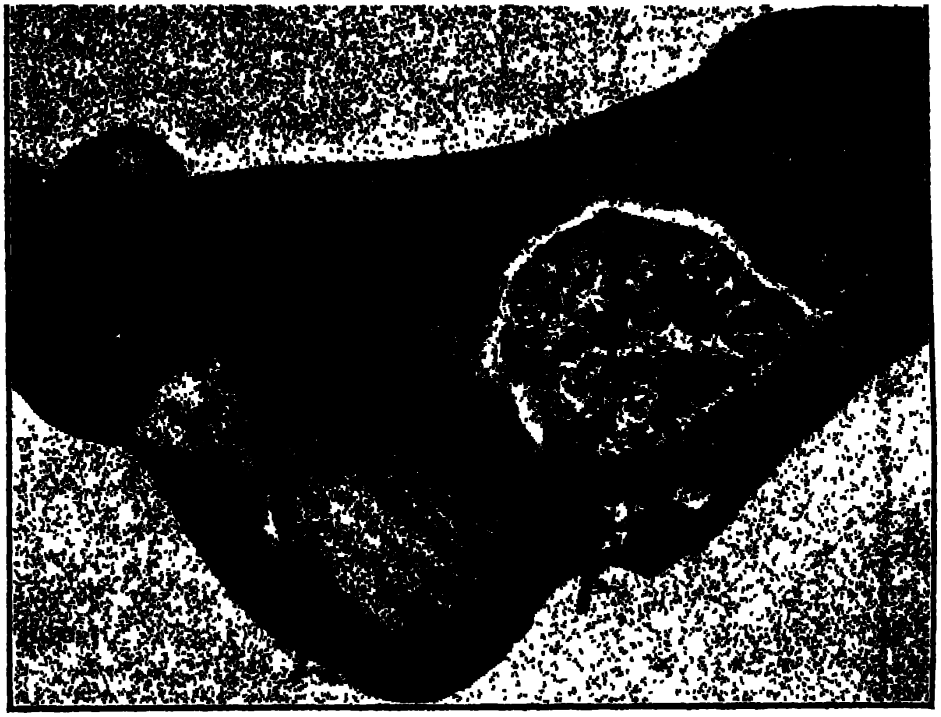

FIG. 862.—ULCUS TROPICUM, WITH CORNU CUTANEUM.

The details of the treatment are found in the chapter on Frambœsia (p. 1550). Mercury and potassium and sodium iodides are useless, but calcium iodide (gr. iii.), well diluted, three times daily, seems occasionally to be of some slight benefit. As regards local treatment, the patient, whenever possible, being kept at rest, the dirty greyish, foul-smelling secretion is removed by using a disinfecting solution, such as mercury perchloride, 1 in 1,000; cyllin, 1 in 300; hydrogen peroxide, 10 per cent.; permanganate of potash, 1 in 2,000.

For the first few days it is better not to apply any so-called disinfectant ointments or powders: simply keep the ulcer covered with gauze, moistened as often as possible with one of the disinfecting solutions already mentioned. This generally stops the formation of the greyish, dirty secretion. The ulcer will then appear clean and of a pinkish colour; but whatever be the further treatment used, whether powders (iodoform, boracic acid) or disinfecting ointments (white, red precipitate, or iodoform ointments), the improvement will be very slow, and several weeks, and often months, will elapse before a firm cicatrix is formed. Much quicker results will be obtained by using a protargol ointment. The ulcer is cleaned every morning with a perchloride lotion (1 in 1,000); then a protargol ointment (5 to 10 or 20 per cent.) is thickly spread on a piece of lint or gauze and applied to the ulcer, which is then fairly firmly bandaged.

The superiority of the protargol treatment over other kinds of local treatment is patent in many cases. Castellani, who introduced it for ulcus tropicum, made the following experiment: in a patient presenting two ulcers of little difference in size and deepness, one on the right leg, one on the left, he treated the one on the right leg, which was slightly larger and deeper, with protargol, and the one on the left leg with iodoform. The ulcer treated with protargol healed in three weeks, the one treated with iodoform in two months.

A silver nitrate ointment (½ per cent.), or a silver nitrate (½ per cent.), balsam of Peru (2 per cent.), ointment may also be used.

To accelerate cicatrization allantoin preparations have been used, and also scharlachroth powder. Salvarsan has been used locally as a powder, but this method is not advisable, as it induces a very severe, painful inflammation. Bougey and Vincent recommend a powder consisting of 10 parts of fresh hypochlorite of soda and 90 parts of boric acid.

ULCUS INTERDIGITALE.

This affection is not rare among natives. It was described in 1909 by Castellani, whose work has been recently confirmed by Breinl, Martinez and Lopez. The patient complains of some itching between the toes, though no papules or vesicles are seen. After a few days a fissure appears, which rapidly deepens, and enlarges into a large oval ulcer with a dull, dark red fundus and sodden-looking margins. There is practically no discharge whatever. The ulcer is generally very painful. The skin surrounding the ulcers does not show signs of inflammation. Under proper treatment the ulcer heals in a few days. The patient must remain at rest, washing the ulcer twice daily with a 1 per cent. carbolic lotion, followed by dressing with a bismuth-boric acid ointment:—

Bismuthi subnitratis	gr xxx.
Acidi borici	gr. xv.
Vaseline	℥i.

ULCUS INFANTUM.

Historical and Geographical.—Under this name Castellani described a rather rare ulcerative condition of the legs met with in Ceylon among children, both native and European. His researches have been confirmed by various observers, among whom Gabbi and Sabella in Tripoli. The condition is found in Ceylon, India, and North Africa.

Ætiology.—This is unknown. A bacillus which cannot be grown is the only germ present in most cases; but as to its ætiological rôle nothing can be said definitely.

Symptomatology.—A reddish spot appears on some part of the leg. The spot becomes slightly elevated, and shows a yellowish central point. The yellowish point breaks down, and a small ulcer appears, generally of circular shape, and with a red fundus. The ulcer secretes a yellowish, thickish secretion, which dries into a yellow crust. If after some days the crust is removed, the ulcer will be found much larger and deeper—the size of a shilling to a half-crown piece. The ulcer is generally indolent, except on pressure. There may be a little pruritus. The ulcer may be single or multiple. The inguinal lymphatic glands may become enlarged, and occasionally the child has fever. The duration is between four to six weeks and three or four months. On healing, a permanent whitish scar is left.

FIG. 863.—ULCUS INFANTUM.

Diagnosis.—The ulcus infantum is differentiated from ulcus tropicum by the less severe symptoms, by being almost always multiple, by the smaller dimensions of the sore, by the absence of spirochætes, and by the absence of any tendency to phagedæna. In contrast to veldt sore the ulcers are deep, and the crust very thick. No streptococcus is found.

Treatment.—Touch the ulcers with pure hydrogen peroxide once every other day, and dress them with simple boric acid lotion (2 per cent.).

REMARKS ON ULCERS.

Ulcerative conditions of the skin are extremely common in the tropics. They may be classified as follows:—

1. Cutaneous leishmaniasis.
2. Ulcus tropicum.
3. Ulcus infantum.
4. Veldt sore.
5. Ulcus interdigitale.
6. Gangosa ulcers.
7. Leprotic ulcers.
8. Ulcers of frambœsial origin.
9. Elephantoid ulcers.
10. Blastomycetic, sporotrichitic, acladiotic, and, generally, hyphomycetic ulcers.
11. Cancerous and sarcomatous ulcers.
12. Tubercular ulcers.
13. Syphilitic ulcers.
14. Glanders ulcerations.
15. Ulcers of pyogenic origin (pyosis tropica).
16. Ulcers due to varicose veins.
17. Undetermined chronic or subchronic ulcerations.

The ulcerative conditions which may be considered as strictly tropical and well defined, such as Oriental sore, ulcus tropicum, etc., have already been described. The *cosmopolitan ulcerations*, such as the syphilitic ones and those due to varicose veins, show the same characters in the tropics as in temperate zones, except that very often, owing to their being neglected for a long time, they may present enormous dimensions, and may show secondary infections and become phagedænic. Ulcers due to varicose veins are very common among rickshaw coolies, who have to run and stand for hours at a time. It is remarkable how quickly they heal in most cases in these coolies, if the patient is kept at rest for some time; whereas in temperate zones the healing of varicose veins ulcers is of very long duration.

Undetermined Subchronic and Chronic Ulcers.

Knowledge of this group of ulcers is scanty, but the investigations of Strong, Stitt, Rho, Wherry, and Clegg, and others have thrown some light on this subject. Our experience tallies with that of Stitt, and we therefore consider that such ulcers may be roughly divided into three groups:—

1. Septic Ulcers—Ulcerations following on Neglected Wounds.
2. Painless Chronic Ulcers.
3. Diphtheroid Ulcers.

Septic Ulcers—Ulcerations following on Neglected Wounds.—These are of pyogenic origin and often very large dimensions. They are generally of roundish or irregular shape, and may be very deep. The secretion is abundant, purulent, and contains the various staphylococci. If the pus is removed, and a scraping taken from the fundus, the preparation will show numerous polymorphonuclear leucocytes and various cocci. These ulcers do not show tendency to spontaneous cure, but heal quickly under an antiseptic treatment. We generally treat them with hydrargyrum perchloride (1 in 2,000). The opsonic treatment also gives good results.

Nichols has called attention to discharging sores in the Philippine Islands, called 'puente,' which are produced by the natives applying some lime to the skin, and afterwards betel powder, with the object of counter-irritation.

Painless Chronic Ulcers.—A small red scaly, slightly itching spot appears, generally on the legs, and gradually enlarges for about four to eight weeks, when the affected area begins to exude a serum which quickly dries into crusts. Under the crust ulceration slowly takes place. At first the ulcers are shallow, and may have undermined edges: later they are often punched out, and may become indurated. There is no pain, except slight pain on pressure, and the general health is not affected. Healing takes place under the crust, and lasts between two and twelve months. A pale cicatrix, with hyperpigmented margins, is left.

As noted by Stitt, scrapings from the fungus show a prevalence of mononuclear cells, polymorphonuclears being practically absent. No pyogenic organisms are found.

Treatment.—The treatment is difficult. Cauterization does very little. In some cases the application of bismuth subnitrate, xeroform, novoform, dermatol, and firm bandaging is useful. In others a protargol ointment (5 to 10 per cent.), or a nitrate of silver (½ per cent.) balsam of Peru (1 per cent.) ointment is of advantage. Allantoin preparations may also be used. When the ulcers are very large and atonic, skin transplantation may be necessary.

Diphtheroid Ulcers.—An angry red, painful spot, often surrounded by vesicles, appears on the legs. Within a few hours—twelve to forty-eight—the affected area is turned into a dark greyish or blackish membrane. If this membrane be removed, an ulcer will be found covered with greenish pus. The membrane reforms rapidly, and, apart from the dark colour, it closely resembles a diphtheria membrane. These ulcers extend rapidly, but do not take, as a rule, a true phagedænic character. The margins after some time may become indurated, but do not show a punched-out appearance. Scrapings taken from the fundus show numerous polymorphonuclears. The course is very long. These ulcers are with difficulty distinguishable from true ulcus tropicum except by the absence of *Spiroschaudinnia vincenti* Blanchard.

Treatment.—Excision is not to be advised, as in Stitt's and our own experience, when this has been done, additional lesions have appeared. Bier's passive congestion method is painful, and does not improve the condition. On the whole, the best treatment is to keep the ulcers well disinfected with a perchloride lotion (1 in 2,000), occasionally touching them with pure hydrogen peroxide. Should the ulcers become phagedænic, the application of pure carbolic is advisable.

GRANULOMA INGUINALE.

Synonyms.—Ulcerating granuloma of the pudenda, Granuloma Venereum (Brooke), Esthiomène de la vulve.

Definition.—Granuloma inguinale is a chronic granulomatous affection of probable protozoal origin attacking the generative organs, from which it spreads to the inguinal regions and the perineum.

History.—In 1896 Conyers and Daniels described a disease of the generative organs in both men and women in British Guiana which was very painful, disfiguring, and contagious. Daniels thinks that it was previously described by Macleod and Maitland in India. Since then papers have appeared on the subject by Ozzard, Galloway, Wise, Donovan, Siebert, Flu, Martini, Gabbi, Sabella, Torres, Rabello, Pijper, Mayer, Newham and Low, and many others.

Climatology.—It occurs in British Guiana, the West Indian Islands, West Africa, South Africa, India, South China, and Northern Australia; but is rare in Ceylon, Malaya, Sudan, and Central Africa. It has been reported from Northern Africa (Tripoli) by Gabbi and Sabella. A similar or identical condition has rarely been met with in Europe and North America.

Ætiology.—It appears in the genitalia of both sexes after puberty, but is rare after forty-five years of age.

Donovan, in 1905, described certain peculiar rod-like bodies 2 μ by 1 μ, lying singly or in groups in mononuclear cells, obtained by scraping the sores. Donovan stated that the bodies looked 'like gigantic bacilli with rounded ends,' but left the nature of them undecided. Siebert, in 1907, carried out an investigation on material originating from various countries, demonstrating the same or similar bodies in all instances, but referring to them as *diplococci*.

Markham Carter, in [illegible] described the parasites as 'bean-shaped bodies resembling the gregariniform stage of a herpetomonas or a crithidium,' and came to the conclusion that the affection was due to either a herpetomonas or a crithidium.

Flu, in 1911, in South America confirmed Siebert's work, but considered the bodies to be bacilli, with capsules, and not cocci. At the same time, however, he called attention to the possibility of the bodies being a stage of a chlamydozoal infection. Martini, in 1913, announced that he had succeeded in cultivating the germs described by Siebert and Flu on blood agar. He described them as anaerobic, capsulated, Gram-negative diplococci, and stated that he had succeeded in producing granulomata in mice by inoculation of cultures, though he failed with guinea-pigs and rabbits. In the same year Aragão and Vianna also stated that they had succeeded in growing the bodies, which they considered to be of bacterial nature, using the term 'calimmato-bacterium granulomatis.' Their work was confirmed by De Souza Araujo.

It is very doubtful whether the cultures obtained by all these observers are in reality cultures of Donovan's bodies. The inoculation of vaccines made from such cultures do not induce any improvement.

Wise, in 1907, found in the eruption spirochætes resembling *Treponema pallidum* and *Spiroschaudinnia refringens*, together with small bodies consisting of a thin capsule surrounding a clear unstained space, in the middle of which was a curved chromatic rod, which was thinner in the centre and club-shaped at either end. He found from two to twenty five of these in the leucocytes. Cleland confirmed Wise's observations, and called the spirochæte *S. aboriginalis* Cleland, 1909.

Bosanquet confirmed the presence of spirochætes in sections, associated with numerous bacteria, but did not consider the spirochætes to be the ætiological agents of the affection. De Souza Araujo observed that after the injection of salvarsan the spirochætes disappeared, but the condition did not get better; hence he came to the conclusion that the spirochætes had nothing to do with the ætiology of the disease.

Cleland and Hickinbotham, in 1909, published further observations on granuloma inguinale, and stated that spirochætes were present only in a certain number of cases, while they constantly found large numbers of diplobacillary bodies. Le Dantec, in 1911, was still of opinion that the malady was of tubercular origin. Torres and Rabello believed it to be a form of sporotrichosis, and Greco a blastomycosis. Pijper, in a recent interesting publication, has definitely brought forward a chlamydozoon theory, and considers that the variously shaped bodies described by so many observers are stages of the same organism, a stage of which, in Pijper's opinion, closely resembles the initial or elementary bodies described by Prowazek in the development of the Guarnieri bodies.

Communicability.– The disease is generally transmitted by sexual intercourse.

Cleland states that in West Australia the malady is especially common among 'gins' (native women), and there is an idea prevalent among the white settlers that the girls become infected by connection with dogs, in which animals a condition similar or identical with granuloma venereum is said to be found. Ernest Black, who has made a thorough investigation, states that Cleland's hypothesis is untenable.

Pathology.—According to Galloway, the microscopical changes begin some distance from the lesion, and consist of a round-celled infiltration into the upper regions of the corium. This induces the papillæ to increase in length, thus producing the typical papule, and at the same time causes an elongation of the interpapillary processes of the epidermis, until they are some eight or ten times their original length.

The connective tissue of the corium swells and disappears, and its place is taken by a round-celled infiltration, which consists of leucocytes, Unna's plasma cells, mast cells, and connective-tissue cells. Giant cells are not found. The leucocytes are the ordinary polymorphonuclear leucocytes, while Unna's cells are characterized by possessing a rounded nucleus, with a certain amount of surrounding protoplasm containing basophile granules. The connective-tissue cells are spindle-shaped. The cells of the epidermis are modified over the papule by becoming swollen, hyaline, and showing mitosis. The stratum granulosum fails to develop its kerato-hyalin granules, and eventually disappears halfway up the papule, as does the stratum corneum, so that on the summit the different layers of the epidermis cannot be differentiated.*

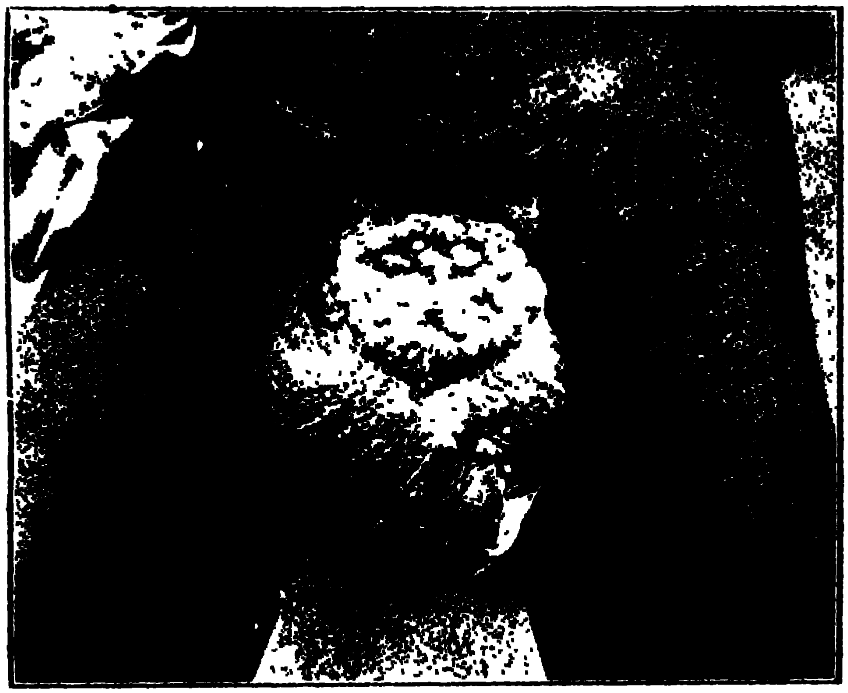

FIG. 804.—GRANULOMA INGUINALE.
(From a photograph by Sambon.)

There is neither caseation nor suppuration, but in the older parts of the specimen the cells of the infiltration become swollen and disappear, and in their place there appears cicatricial connective tissue, which causes the papule to shrink and the whole area to assume a scar-like appearance.

Symptomatology.—The disease in the male begins on the penis, as a rule, as a papule or small nodule, which extends over skin and mucosa by peripheral growth, which is aided by the formation of new papules and nodules at the growing margin and in the healthy skin. It grows into the groins, causing the hair to fall out, and between the scrotum and the thighs, and from thence backwards into the perineum and around the anus, into which it may pass.

When fully developed, it appears as a mass of nodules or papules, without deep ulceration as a rule, but with a thin, offensive discharge. In the older regions it shows some attempt at healing in the formation of dense scar tissue. There is very little pain or pruritus.

In the female the process begins as a papule on the labium minus, and then extends into the vagina, along the perineum, around the anus, and up the rectum, and into the groins. The growth extends into the tissue between the rectum and the vagina, and may give rise to rectovaginal fistulæ. The whole growth is also much more liable to ulcerate in the female than in the male.

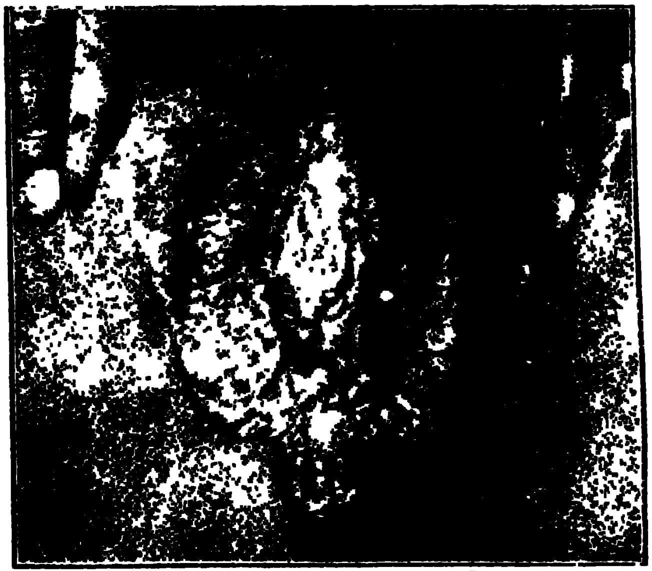

FIG. 865.—GRANULOMA INGUINALE.
(From a photograph by Sambon.)

The lesions may become œdematous, and present an appearance analogous to elephantiasis.

Bonne and Verhagen have described a case in which the disease after a time attacked the upper lip and alæ nasi.

Varieties.—Daniels lays stress upon the fact that the disease varies much in different races. In negroes it is more granular, and spreads farther; in Indians it is less marked; in Fijians it is softer, and separate areas more common.

Diagnosis.—It is most likely to be confused with syphilis, lupus, and epithelioma. From syphilis it can be differentiated by the absence of the secondary eruption and the inefficacy of mercurial treatment. Lupus is very rare in such situations, and in epithelioma the lymphatic glands would be early infected. In doubtful cases microscopical examination of a piece of the diseased tissue will enable the diagnosis to be made from lupus as well as from epithelioma.

Prognosis.—The disease as a rule does not affect the general health, but is extremely chronic, lasting for years.

Treatment.—Tartar emetic, though not efficacious in every case, should always be given a thorough trial. The treatment is carried out in the same way as for cutaneous leishmaniasis (see p. 2173).

Tartar emetic was first used in granuloma inguinale in 1913 by Arago, Vianna, and De Souza Araujo. Breinl and Priestley confirmed the work of these observers in a case in Australia, and very shortly after Newham and Low in a case in Europe. Low, however, reported later on a complete failure of the tartar emetic treatment in another case.

Greig and Cujel consider that tartar emetic benefits the condition only when given in very large doses; according to them the drug acts, not as a true specific, but as a general protoplasmic poison.

The best local treatment is radiotherapy with X rays which has been found quite successful in Madras. If these are not available, antiseptic lotions should be applied, and then portions excised, or the diseased areas may be scraped and then cauterized. Convers and Daniels recommend the application of an ointment of salicylic acid (gr. xxx.), unguentum creosoti (℥i.).

Certain observers claim to have had good results with salvarsan and neosalvarsan. The technique of the treatment has been described in the chapter on Frambœsia (p. 1500). Large doses of potassium iodide are said to be useful.

PAPILLOMA INGUINALE TROPICUM.

Synonym. Acanthoma Inguinale (Castellani).

A peculiar papillomatous affection of the inguinal regions is not rare among Tamils. Further experience will probably show that other races are also affected. Women are apparently more liable to the disease than men, inasmuch as, although the number of male patients in the Colombo Clinic and hospitals is much larger than the number of female patients, not a single case has been detected among men.

Symptomatology.—One or both inguinal regions are occupied by extremely numerous tall filiform vegetations of a pinkish or darkish colour. No ulcerative lesions are present. There is neither pain nor pruritus. The general health does not seem to be affected. The affection is very chronic, and is probably contagious, but nothing is known of the ætiology. In the cases so far observed the genital organs of the patient were normal, and there was no history of gonorrhœa or any other venereal disease.

Treatment.—The treatment is surgical—removal of the vegetation by the knife and cauterization. The patient, as a rule, however, will not consent to the operation.

CHAPTER XCVI

THE DERMATOZOIASES

Classification—Hexapode dermatites—Creeping eruption—Circinate creeping eruption—Dermatitis macrogyrata—Chilopode dermatites—Acarine dermatites—Copra itch—Grain itch—Scabies—Nematode dermatites—Cestode dermatites—References.

CLASSIFICATION.

THE term 'dermatozoiasis,' in the widest sense of the word, means any skin disease of animal origin, but it is usually restricted to indicate those skin lesions which are caused by metazoan parasites. Used in this restricted sense, dermatozoiasis includes:—

I. Hexapode dermatites.
II. Chilopode dermatites.
III. Acarine dermatites.
IV. Nematode dermatites.
V. Cestode dermatites.

I. HEXAPODE DERMATITES.

The Hexapode Dermatites include the lesions of the skin caused by either the bites, the stings, or the presence of the larvæ or the pregnant female of various species of the *Hexapoda*.

These hexapode dermatites may be divided into four classes.—

1. Dermatites caused by bites of the adult.
2. Dermatites caused by blistering fluids excreted by the adult.
3. Dermatites caused by stings of the adult.
4. Dermatites caused by the presence and bites of the larvæ.
5. Dermatites caused by the presence of the imago.

||1. Dermatites caused by Bites of the Adult.

These lesions are most commonly due to bites of species of the families Pediculidæ (p. 753); Clinocoridæ (p. 762); Anthocoridæ (p. 766); Reduviidæ (p. 767); Aradidæ (p. 770); Culicidæ (p. 774); Psychodidæ (p. 806); Simuliidæ (p. 810). Tabanidæ (p. 817); Muscidæ (p. 831), and by species of the orders Siphonaptera (p. 837) and Hymenoptera in which comes the family Formicidæ, or ants (p. 222).

The bites of these insects are either considered in pp. 223-226, or in the references given above, and need not be further considered except with regard to the Pediculidæ. which cause the dermatosis called Pediculosis.

Pediculosis.

Synonyms.—Phthiriasis, Vagabond's disease.

Definition.—Pediculosis is a term applied to the various lesions primary and secondary, induced by the bites of *Pediculus humanus* Linnæus, 1758, *Pediculus corporis* de Geer, 1778, and *Phthirius pubis* Linnæus, 1758 (pp. 755-757).

Remarks.—Pediculosis is extremely common in the tropics, where it is an everyday sight to see the lower-class natives busily employed in killing the lice in their friends' heads. It is also commonly present in all armies on active service, and as lice are carriers of such diseases as typhus, relapsing fever, and trench fever, etc., they have assumed a very important position in the recent war.

Ætiology. Pediculosis is due to the irritation caused by the venom injected during the bites of the three species of lice mentioned in the definition.

Pathology. -The mouth parts of a louse consist of two tubes one inside the other: the outer chitinous tube, called the *proboscis*, is composed of the fused labrum and labium, and is armed with a collar of minute curved hooklets, while the inner membranous tube is composed of the maxillæ and mandibles, and is called the *suctorial tube*. When about to bite, the louse inserts its hard proboscis into a sweat duct, everts its small hooklets, and thus obtains a hold upon the skin. It then protrudes the suctorial tube, which it drives deep into the skin of the host until it reaches the blood. It is during this process that it probably injects the venom from its salivary glands, but the nature of this poison is quite unknown, although its presence is with reason suspected owing to the pruritus caused by the bites of the lice.

Having reached the blood, it proceeds to fill itself to repletion, pumping the blood into its alimentary canal by means of the chitinous pharyngeal pump. After feeding, it withdraws its proboscis, and the blood fills up the orifice and coagulates, forming a minute red papule. Considerable pruritus is now felt, and the victim scratches vigorously to relieve this sensation, and often produces marked excoriations, which may become secondarily infected with the common pyogenic cocci, causing purulent lesions. Repeated biting, associated with injection of the venom, and constant scratching, leads to pigmentation of the skin, causing the so-called pityriasis nigra of Willan, or melanoderma pediculis. If this process is continued, the skin becomes thickened and deeply pigmented, and forms the so-called 'vagabond's disease.' The pigmentation is naturally not observable in very dark skins, and may not be so entirely dependent upon the scratching as is usually stated, but may be, in part at least, caused by the venom.

Symptomatology.—The essential symptom is pruritus, which need not be localized, but may be general, accompanied by the presence of the minute papules with bright red centres, but this simple picture is generally complicated by the erythema or excoriations set up by the scratching induced by the pruritus, and this again may be complicated by the appearance of pustules, due to secondary pyogenic infections, which dry and leave scabs. In these cases the neighbouring lymph glands are usually enlarged. Very rarely may pediculosis give rise to general symptoms, such as fever.

Varieties.—Three clinical varieties of pediculosis are described—viz., pediculosis capitis, pediculosis corporis, and pediculosis pubis.

Pediculosis capitis is caused by *Pediculus humanus* Linnæus, 1758, which, though usually confined to the hairy regions of the head, may rarely be found in other parts of the body. They are grey on Europeans, and brownish or even black in colour upon dark-skinned natives, and are said to be yellow on Chinese, and orange-coloured on Hottentots. They often infect European ladies, probably coming from the native ayahs, and thus a very dark pediculus may be found on a fair European. They cause intense irritation of the head, and may give rise to secondary impetiginous lesions and enlargement of the lymphatic glands, especially those of the back of the head, and in very dirty people with long hair they may cause the peculiar condition of matted hair called 'plica polonica.'

Pediculosis corporis.—This is caused by *Pediculus corporis* de Geer, 1778. These pediculi live in the clothing, especially in thick seams, and are therefore to be found on natives in the region of the waist, where the clothing is twisted into a thickish roll. In Europeans the most common site for their attacks is the back of the shoulders, where the small papules with the bright red centres and the linear scratches may be seen.

Pediculosis pubis.—*Phthirius pubis* lives wherever there are large thick hairs—viz., on the hairs of the pubis, or the eyelids or eyebrows, and of the beard and armpits. Here again it is accompanied by the characteristic signs. In addition, Morrison's spots or maculæ ceruleæ may be seen in the form of small, roundish or oval greyish-blue maculæ, which are thought by some authorities to arise from the pigment on the thorax of the louse opposite the anterior pair of legs, but which more probably arise from the action of the venom. The reddish deposits seen on the hairs are said to be the fæces of the parasite. The eggs may be seen as small, oval bodies attached to the hairs.

Diagnosis.—The diagnosis depends upon the history of pruritus of a more or less severe type, usually worse in some given region, and by the appearance of scratches associated with the little papules and the discovery of the lice on the body or in the clothing, which must be that usually worn by the patient. The rare diffuse pigmented forms of pediculosis may be mistaken for Addison's disease or the suprarenal form of malaria, but may be recognized by the finding of the lice, the non-diminution of the muscular power, and by the presence of the pruritus. From scabies it may be distinguished by the lack of lesions on the hands and wrists, and the absence of the sarcoptes.

Treatment.—*Pediculosis capitis* may be treated by soaking the hair with petroleum (care being taken not to approach a light), followed by a good wash with soap and water, the whole process being repeated in twenty-four hours. Another method is to sponge the hair little by little with carbolic acid (1 in 40), or soak long hair in carbolic lotion (1 in 80) followed by a good wash with soap and water, and later by a lotion of acetic acid (25 per cent.), used to loosen the eggs, which are then removed by the use of a small-toothed comb.

Another method of killing the parasites is by dabbing the hair with xylol, remembering, however, the danger of fire with this inflammable substance.

Impetigo contagiosa may be treated by an ointment composed of ammoniated mercury (5 grains) and lard (1 ounce), and in children the hair may be cut and this ointment may be applied.

Pediculosis corporis.—The clothing and the bedding must be disinfected by steaming or boiling, and the patient must have several large baths, with free use of soap and water, as well as a soothing calamine lotion (40 grains calamine to 1 ounce of water) for application to the irritated skin. Lice destruction is more fully detailed on pp. 1338, 1339.

It is important to remember that the eggs of *P. corporis* are often attached to the lanugo hairs. Merely cleaning the clothing is often useless. Rub or spray the whole body with paraffin and take a warm bath.

Martini recommends a depilatory consisting of strontium sulphate 2 parts, zinc oxide 1 part, talc 1 part. This is mixed with a little water and applied as a paste for ten minutes, when it is removed and some olive oil used to soothe the irritation.

Pediculosis pubis.—A white precipitate ointment (5 to 10 per cent.) or an ointment of oleate of mercury (5 per cent., 6 drachms) with ether (2 drachms) will kill parasites and ova, after which calamine lotion may be applied to allay the irritation.

Clinocorosis.

Bugs produce wheals, with central red spots surrounded by zones of hyperæmia. A solution of menthol (5 grains in 1 ounce of rectified spirits) will relieve the irritation; or, if the area has been scratched, the application of a lotion of carbolic acid (1 in 40) is preferable. As regards prophylaxis, see p. 765.

Siphonapteriasis.

Flea-bites are characterized by small red papules with dark red centres, and are to be distinguished from the maculo-papules of enteric fever, which disappear on pressure. The linen of a person probably suffering from flea-bites should be inspected for the brown fæcal marks made by the fleas. For further details, see pp. 857 and 908. To keep these pests away, some powdered camphor may be used.

Formiciasis.

Ant-bites usually only produce local pain, inflammation, and swelling; but the larger tropical ants may cause faintness, shivering, and even temporary paralysis by their bites. In Ceylon the very small ants, which infest the beds, produce urticarial pomphi. These bites are best treated by applying a solution of carbolic acid (1 in 20), and as a preventative against ants infecting beds some powdered camphor may be dusted in the sheets (see p. 222).

2. Dermatites caused by Blistering Fluids excreted by the Adult.

The insects which act in this manner are the well-known '*blister beetles*' (*vide* p. 226), which cause the eruption called 'Seasonal bullous dermatitis' (synonym, Seasonal vesicular dermatitis), which we will now describe.

SEASONAL BULLOUS DERMATITIS.

Definition.—Seasonal bullous dermatitis is characterized by an epidemic of bullæ of varying size and shape in healthy people at a definite season of the year. The bullæ or blisters are followed by sensations of itching, burning, or pain, and are caused by blister beetles.

Historical.—Beetles have been known to cause blisters and eschars on the skin since the days of Archigenes, a contemporary of Celsus, or, according to other authors, since the time of Aretæus the Cappadocian. Pliny says that authorities differ as to the origin of the blistering fluid, some thinking that it comes from the mouth and others from the feet. Moffat, in 1634, wrote a long chapter on these insects, and Linnæus, Fabricius, and Latreille gathered together quite an amount of information on these beetles and their varieties.

In 1890 Beauregard wrote a large book on 'Les Insectes Vésicants,' but notwithstanding all this ancient and modern knowledge works on tropical medicine were singularly silent on the subject.

In 1912 P. Da Silva drew attention to an outbreak of this eruption among cultivators on the banks of the rivers São Francisco, Itapicurû, and Jacuricy, in the interior of Bahia, which was traced to a vesicant beetle, *Pæderus columbinus*. In 1913 Adolf Eysell mentioned *P. peregrinus* as the cause of the same eruption in the island of Sunda, in the Malay Archipelago. In 1915 Rodhain and Houssiau saw the disease in Léopoldville, in the Belgian Congo, and Bequaert at Boma. In 1916 P. A. Ross noted it at Nairobi, in British East Africa, and in 1917 Chalmers and King gave an account of its occurrence in Khartoum, Anglo-Egyptian Sudan.

Ætiology.—The blisters are caused by the fluid which exudes from the joints of the legs, especially the so-called knee-joint of certain species of insects belonging to the order *Coleoptera* Linnæus, 1735, and to the families *Staphylinidæ* Leach, 1817, and *Cantharidæ* Leach, 1817. The following is a list of those known to cause the complaint, though doubtless many more insects can do so equally well:—

Staphylinidæ :—

Pæderus columbinus de Laporte, 1832.
Pæderus peregrinus Fabricius, 1801.
Pæderus cerebripunctatus Epp (?).

Canthuridæ :—

Epicauta sapphirina Macklin, 1845.
Epicauta tomentosa Macklin, 1845.

The seasonal occurrence is due to the fact that the adult insects are only present for a limited period in the year, the remainder of which is occupied by the long and complicated development.

Symptomatology.- So long as the insect merely walks over the skin, and is not irritated, it does no harm. If, however, it starts to crawl up the arm, down the neck, or up the trousers, it is soon annoyed by the clothing and excretes the blistering liquid.

If only a small quantity of this fluid is ejected, then only a single small bulla may form, but if the insect moves a series of these may be produced. If, however, the blistering fluid is well rubbed into an area, then an eschar forms, with considerable surrounding irritation. Occasionally, instead of a series of blisters, one long blister may extend a considerable distance along the forearm or down the back.

Usually there are no immediate symptoms, and it is only after an interval of twelve to twenty-four hours that an itching or burning sensation, or even severe pain, invites attention to the affected area, when the blister or blisters, varying in size and number, as already stated, are to be found full of yellowish serum and situated on an erythematous areola.

As a rule the victim does not see the insect and may not remember one crawling on him, and he may be entirely at a loss to account for the blisters. It is here that the difficulty of diagnosis arises in that the practitioner may see only one or two cases, and at the moment may not think about these insects.

If pricked and carefully treated, they quickly vanish and cause no further trouble: but if they burst, and are allowed to be rubbed by the clothing, they become raw, very tender, and painful a condition which may last for days.

More rarely a considerable portion of the blistering liquid appears to get well rubbed into one spot, and then a small white eschar is formed which may be surrounded by an extensive inflammatory areola, with its surface raised above the central necrotic area and covered with numerous small red papules. The whole region becomes very painful and tender, and some couple of weeks elapse before healing is completed, which generally takes place without any cicatrization. Secondary septic infections are rare. After being *en evidence* for some three to four weeks, the beetles disappear and the epidemic ceases for the year.

Diagnosis.—The characteristic features of seasonal bullous dermatitis are as follows:—

1. The sudden appearance of bullæ, varying in size and number, surrounded by a certain amount of inflammatory redness.

2. The persons in whom the bullæ are found are usually in good health, and as a rule they are unable to assign a cause for the eruption.

3. The bullæ are single or grouped together, often in a row.

4. There is no tendency to bilateral symmetry.

5. In a given individual usually only one region of the body is affected.

6. A number of healthy people living in the same place may be similarly affected at the same time.

7. The bullæ only appear during a certain season of the year.

The differential diagnosis requires to be made from the following accidents and diseases causing bullæ:—

1. Seasonal bullous dermatitis may be readily separated from the bullæ caused by burns and scalds, and by chemicals, by the history of the case.

2. It has also to be differentiated from the various forms of Hydroa as follows:—

(*a*) It can be separated from the milder forms of dermatitis herpetiformis by the absence of severe itching and of circinate and papular erythematous lesions, and by the absence of the tendency of the bullæ to be grouped like herpes.

(*b*) From the rare form of dermatitis herpetiformis called hydroa pruriginosa it can be diagnosed by the larger size of its bullæ, which do not appear in successive crops.

(*c*) From dermatitis recurrens it can be distinguished from the hiemal variety by only appearing in warm weather, and from the æstival in not being papulo-vesicular in character.

3. It may be differentiated from herpes zoster by the absence of severe pain, lasting for three to four days before the appearance of the eruption, and by the non-distribution of the bullæ in Head's areas.

4. From Acute Pemphigus it is easily separated by the absence of the severe constitutional symptoms.

5. It can be recognized as distinct from dermatitis venenata, due to plants, by the absence of the marked œdema and erythema, which generally attack the face, hands, and genitalia, and by the presence of bullæ.

6. It is easily separable from Dermatitis caused by mites, as these give rise to small wheals and vesicles, and not to bullæ.

7. Ant and tick bites, stings of wasps, bees, scorpions, centipedes, etc., are at once differentiated because the eruption in the present instance is bullous.

As the eruptions described by Rodhain and Houssiau and by Ross are stated to be vesicular, it is possible that these may be differentiated clinically from this bullous type, while it certainly is not so severe as the eruption described by P. Da Silva, in that ulceration and cicatrization are absent, but perhaps these may be only differences in details and not in essentials.

Prognosis.—This is good. Cases recover fairly rapidly and as a rule without cicatrization, hence the outlook as regards rapidity of cure and the absence of scarring is good.

It will, however, be remembered that P. Da Silva describes a much severer form of dermatitis than that mentioned here, and that this was followed by cicatrization.

Treatment.—The best treatment is to prick the blister and apply a dressing of 1 in 80 carbolic acid, but the majority of the victims just let the lesions alone, and they heal up rather more slowly than when treated and are more painful. If they become rubbed, they are often very painful.

3. Dermatites caused by Stings of Adults.

Stings are mainly caused by species belonging to the family Apidæ of the Hymenoptera, which includes the bees and wasps. A description of these stings will be found on pp. 219-222.

4. Dermatites caused by Larvæ.

The larvæ of various species of the Œstridæ and Muscidæ are compelled to undergo their development in the skin of some warm-blooded animal, and as these are plentiful, as a rule the flies do not attack man, who only occasionally suffers from their effects, and when he does the pathological condition is usually named dermal myiasis (p. 1631). Other larvæ—as, for example, that of *Auchmeromyia luteola* Fabricius, 1805—are blood-suckers.

Blood-sucking Dipterous Larvæ.

Only a very few blood-sucking dipterous larvæ are known, and these belong to two genera, which may be distinguished from one another as follows:—

A. Abdomen long and narrow, with unequal segments and distinctly longer than the thorax—*Auchmeromyia* Schiner and Bergenstamm, 1819.

B. Abdomen short and broad, with equal segments and but little longer than thorax—*Chœromyia*, Roubaud, 1911.

There are two species belonging to the last-named genus—viz.:—

Chœromyia chœrophaga Roubaud, 1911.
Chœromyia boneti Roubaud, 1911.

Neither are known to attack man. They live in the burrows of the wart-hog and the ant-bear in the Sudan. There are also two species belonging to *Auchmeromyia*—viz.:—

Auchmeromyia luteola (Fabricius, 1805).
Auchmeromyia prægrandis Austen, 1910.

Both these may attack man.

Auchmeromyia luteola (Fabricius, 1805) lays its eggs in soil contaminated with fæcal matter or urine around or inside native huts in the Congo (hence its name *Congo floor maggot*), Central and Northern Mozambique, Eastern Transvaal, East Africa, Nyassaland, and Kordofan. The larva, escaping from the egg, seeks the cracks and crevices in the mud floors of these huts or pass into dirty native mats. When hungry, these larvæ are thermotoxically drawn to a temperature of 38° C., and hence they attack man, both biting and sucking blood. When replete, the researches of Roul and show that they are no longer thermophilus. Under favourable conditions the larvæ become pupæ in some fifteen days, but under unfavourable circumstances larval existence may be prolonged for seventy-six days. Only the larvæ are blood-suckers, and they may be killed by sprinkling the floor with Jeyes' fluid.

Auchmeromyia prægrandis Austen, 1910, is found in South Africa.

IRRITATING LEPIDOPTEROUS LARVÆ.

The larvæ or caterpillars of many genera of Lepidoptera are well known to possess tegumentary glands, which secrete an irritating fluid, which passes from the gland to hollow hairs. These are the instruments by which the caterpillar injects this fluid into the skin, causing erythema and irritation.

White gives long lists for Europe and America, while Wellman has studied the subject in Angola, where he mentions larvæ belonging to the Arctiidæ, Limacodidæ, and Liparidæ, and gives details concerning one—viz.:—

Ochipia is a native name signifying 'that which burns,' and is applied to the larvæ of the tiger-moth, which is very irritating.

IRRITATING COLEOPTEROUS LARVÆ.

Wellman says that in Angola there is a coleopterous larva called *Ochisia* (*Noli me tangere*), which possesses bristles which can penetrate into the sole of the foot and cause pain, inflammation, and sloughing. It is related to the genus *Drilus*, of the Malacodermata.

DERMAL MYIASIS.

This subject has been discussed in Chapter LXVII., p. 1631, and need not be further mentioned, except to invite attention to Baier's work, published in 1740, entitled 'De generatione insectorum in corpore humano,' and Clarke's paper in 1797 to the Linnæan Society of London, establishing the relationship between the larvæ and the adult insects in the Œstridæ. Smith's paper at the 1881 International Medical Congress is also of interest.

Creeping Eruption.

Synonyms.—Larva migrans. *Bulgarian :* Nova Bolest, Pulziasta Bolest. *German :* Hautmaulwarf. *Northern Nigeria :* Larbish or Œrbiss.

History.—This disease was first described by A. Lee in 1875. Later on, Procke, Blanchard, Topsent, Füllebørn, Macfie and others have recorded several cases. It is not rare in some parts of Europe, Africa, and Asia, and in South America. We have seen numerous cases in Ceylon. It is extremely rare in North America.

Ætiology and Pathology.—Larvæ of the genera *Gastrophilus*. *G. hæmorroidalis* and *G. nasalis*, *Œstromya satyrus*, *Hypoderma* *bovis*, and *H. lineata* have been found in several cases. In others no larva whatever was found. Looss states that the same clinical picture may be caused occasionally by ancylostoma and strongyloides (*Anguillula*) larvæ, or even by an inanimate object like a piece of horsehair.

Fig. 866.—Larva Migrans.

Symptomatology.—The eruption is characterized by the presence of a narrow raised red line, $\frac{1}{8}$ to 1 inch broad. This line extends daily one or several inches, and is generally sinuous, but may be straight. While the advancing end progresses, the opposite end slowly fades away. The duration of the malady is long—generally several months, but occasionally two or three years. There is much pruritus.

Treatment.—Hypodermic injections of various disinfectants have been tried with little success. Hutchins recommends a cocaine injection, followed by the injection of 1 or 2 drops of chloroform.

Circinate Creeping Disease.

In Ceylon cases are met with of a peculiar eruption, which is possibly of the same nature as the creeping disease previously described, though larvæ were not found.

The condition is characterized by the presence on the back of the hands of a ringed eruption, with markedly elevated, thick, angry, red borders. In all the cases the eruption started suddenly after the patient had been gardening and handling turf. There may be one ring or several. The skin inside the rings is normal. The rings expand excentrically. The patients complain of the extreme irritation, and in all the cases stated that they felt something creeping along the red circles, as though a worm had got inside in handling the turf. The duration varies, but it generally does not exceed two or three weeks.

Ætiology.—The eruption does not appear to be a form of dermatitis venenata, due to touching certain plants and vegetables. Possibly it is due to some larva entering the skin, but so far the search for larvæ has been fruitless. No trichophyton-like fungus is present.

Treatment.—Liq. plumbi and other soothing applications are generally useless. The best results are obtained by continuously applying on lint a diluted alcoholic solution of resorcin:—

Resorcin	ʒi.
Sp. rect...	℥ii.
Aq. dest.	ad ℥xii

Dermatitis Macrogyrata.

Dermatitis macrogyrata is a rare condition found in Ceylon and South India, of unknown causation, and characterized by the presence on the palms of the hands of one or two very large gyrations formed by scaly and crusty lesions. On removing the crusts and scales a broad shallow furrow can be seen situate in the epidermis. The eruption is associated with pain, sometimes severe, but there is seldom any pruritus. The condition is most persistent, and in our cases neither fly larvæ could be found nor fungi isolated. In none of our cases was there history of syphilis, and potassium iodide and mercury had no effect. The treatment is most unsatisfactory. Antimycotic substances, such as chrysarobin and tincture of iodine, have no effect. The application of a lotion of liquor plumbi (ʒii.), tincture of opium (ʒi.) diluted with 8 ounces of water, or of dressing soaked in 0·5 per cent. of resorcin, may cause a slight improvement.

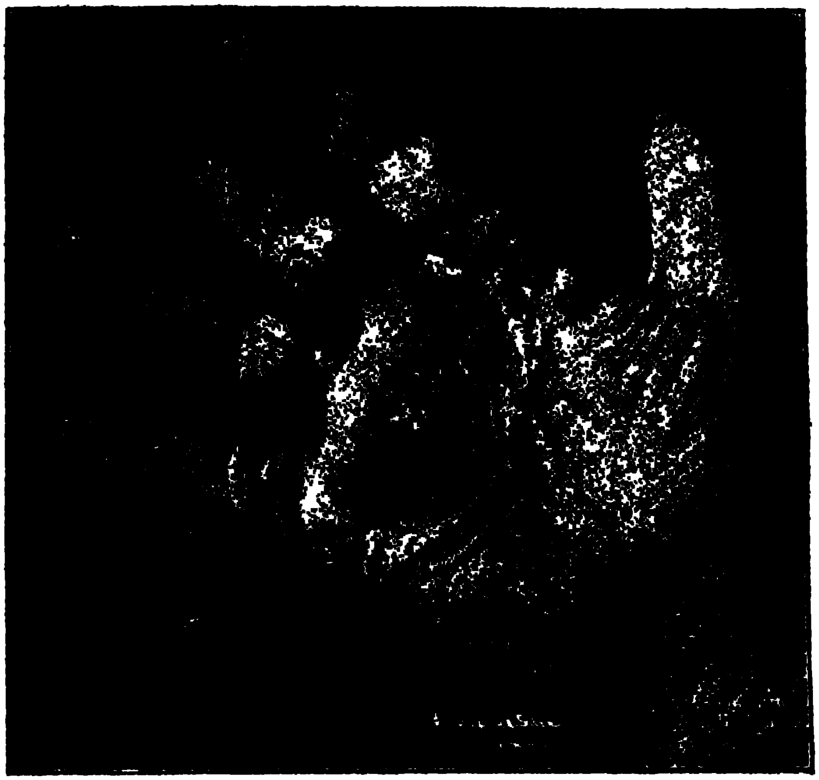

Fig. 867.—Dermatitis Macrogyrata.

5. Dermatites caused by the Presence of the Imago.

At times the impregnated female insect burrows into the skin while the eggs mature.

A good example of this is *Dermatophilus penetrans* Guérin, 1838.

Dermatophiliasis (Jigger).

Synonyms.—Nigua (Honduras), Chique (Salvador), Chica (Columbia), Bicho, Tunga (Brazil), Pique (Argentine), Chique (French Colonies).

Definition.—Dermatophiliasis is the invasion of the skin and subcutaneous tissue by the pregnant female jigger (*Dermatophilus penetrans*).

Remarks.—The home of the jigger is in tropical America, from 23° N. to 28° S., but it and its wanderings over the world have been sufficiently described on p. 862. At present it is found in South America, West and East Africa, Madagascar, Uganda, India, and, it is said, China.

Pathology.—The pregnant female jigger pierces the skin obliquely near the nails and between the toes, but it may occur in any part of the foot, and even on the arms, scrotum, and face. All but the last two segments are embedded in the skin. These last segments plug the orifice and discharge the eggs.

Symptomatology.—The symptoms begin with itching and irritation, generally in some part of the foot, especially the toes, and often under the toe-nail. On inspection, a small dark dot (the last two abdominal segments of the parasite) is noticed in the skin. If left alone, painful inflammation and suppuration develops around the distended abdomen of the parasite, giving rise to a swelling which may attain the size of a small pea, in the centre of which is seen a depression containing the black dot, and, finally, ulceration takes place, and the body of the parasite is thrown off, but not until all the eggs are laid.

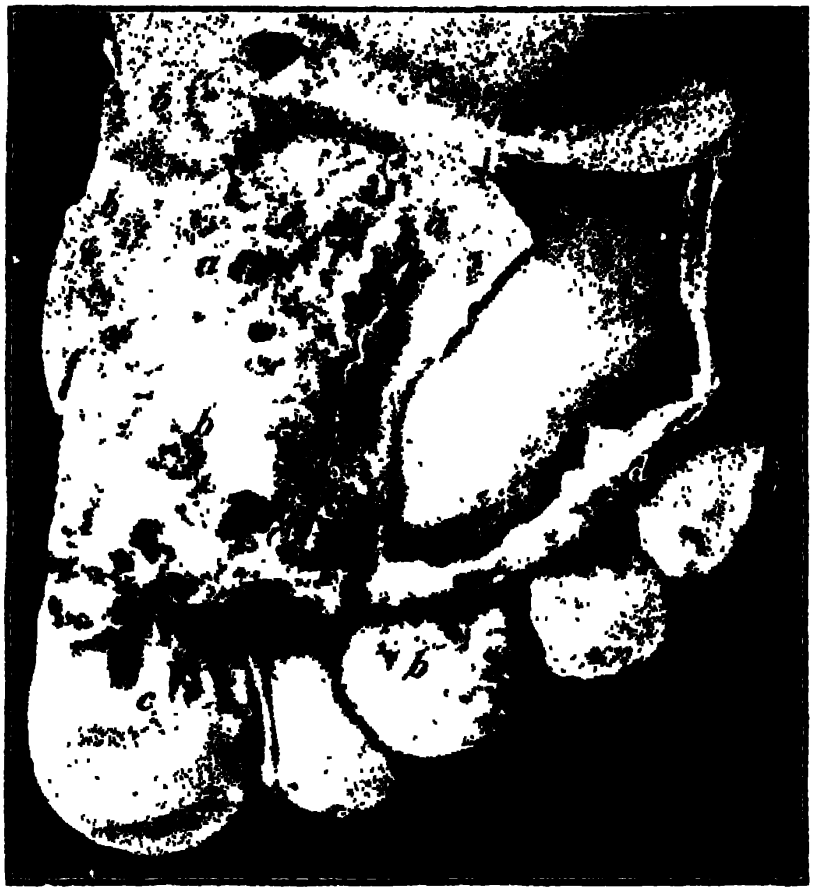

FIG. 868.—DERMATOPHILIASIS. (After Newstead.)

a, Group of jiggers; *b*, isolated jiggers; *c*, pits left by jiggers; *d*, lateral view of jiggers deep in the skin.

When the parasite has been dislodged by treatment or suppuration, a small ulcer is left, which is very liable to septic or other bacterial infections. These infections may lead to phagedæna, gangrene, and tetanus. When the feet are badly affected, walking is impossible, which is of especial importance in carriers and native troops.

Treatment.—The treatment is the careful removal of the little insect with a clean needle, after rubbing weak carbolic ointment (1 per cent.) or lotion (1 to 2 per cent.) into the foot, and cleansing and dressing the little wound antiseptically with a lotion of perchloride of mercury.

In cases of heavy infection, Quirós recommends the use of petroleum, or of an ointment consisting of salicylic acid 1 part, ichthyol 4 parts, vaselin 4 parts.

Prophylaxis.—Prophylaxis consists in keeping the house clean, and pigs, poultry, and cattle kept away therefrom. High boots should be used, and especial care should be taken not to go to a ground-floor bathroom with bare feet. The feet, especially the toes and under the nails, should be carefully examined every morning to see if any black dot can be discovered, when the jigger should be at once removed, and in this way suppuration will be prevented. It is advisable, also, to sprinkle the floors with carbolic lotion, Jeyes' fluid, or with pyrethrum powder, or with a strong infusion of native tobacco, as recommended by Low and Castellani.

II. CHILOPODE DERMATITES.

Centipedes, when they bite, cause local itching followed by intense pain, which spreads over the whole limb when the bite is on an extremity. A red spot appears at the site of the bite, and this enlarges and becomes black, and is sometimes associated with lymphangitis, adenitis, headache, vomiting, dizziness, irregular pulse, and mental anxiety.

The treatment is to bathe the parts with a solution of ammonia (1 in 5 or 1 in 10), and to apply a dressing of the same solution, and if there is much swelling an ice-bag, while if the pain is severe, an injection of morphia may be necessary; while later, fomentations are required for the local inflammation (see also pp. 217-218).

III. ACARINE DERMATITES.

The *Acarine Dermatoses* include the skin lesions caused by the ticks and mites. The tick bites are described on pp. 215 and 217. The mites (pp. 690-693 and 724-732) which most commonly attack man are:—

DERMANYSSINÆ.

Dermanyssus gallinæ de Geer, 1778.

Dermanyssus hirudinis Hermann, 1804.—These mites produce a papular eczematous dermatitis in poultrymen.

Holothyrus coccinella Gervais, 1842, cause a swelling in the part attacked.

TROMBIDIDÆ.

Microtrombidium akamushi Brumpt, 1910, is the cause of Tsutsugamushi disease.

Microtrombidium holosericeum Linnaus, 1746, has a larva (*Leptus autumnalis*) which causes irritation in England in the autumn, and is called the harvest mite. As a fairly effective preservative for this pest the following may be used:—Oil of lavender ♏viii., spirit of camphor ♏xxx., oil of eucalyptus ʒi., soap liniment ad ℥i.

Trombidium tlalsahuate Lemaire, 1867, is the tlalsahuate of Mexico, which, with the allied species called the balata mite of the Guianas, are well-known plagues, burrowing into the skin, and causing intolerable itching and painful little blisters; but the zoological names of these, as well as of the 'pou d'agonte' of Guiana, the 'niaibi' of New Granada, the 'colorado' of Cuba, the 'mouqui' of Para, and the 'bête rouge' of Martinique and Honduras, are not known.

Trombidium wichmanni Oudemans, 1905, is the gonone of Celebes, whose larvæ attack man, burrowing into the skin as just described above.

Trombidium vandersandei Oudemans, 1905, is the gonone of New Guinea, which acts like *T. wichmanni*.

The *Leptus* stage of an unknown *Trombidium* is reported in North Queensland.

TETRANYCHIDÆ.

Tetranychus molestissimus Weyenbergh, 1886, causes severe itching in the Argentine and Uruguay during the months December to February, by thrusting its hypostome into the skin, and thus causes 'Bicho-colorado itch.'

EUPOPIDÆ.

Tydeus molestus Moniez, 1889, is the cause of 'Guano itch.'

TARSONEMIDÆ.

Pediculoides ventricosus Neuport, 1850, is the cause of 'grain itch,' and being a parasite of the pink bollworm of cotton, is found in cotton infested with this pest, and from this source has attacked persons handling the infected cotton in Egypt and England.

Tarsonemus uncinatus and *T. intectus* are also known to attack man.

TYROGLYPHIDÆ.

Tyroglyphus longior Gervais var. *castellanii* Hirst, 1912, is the cause of 'copra itch.'

Tyroglyphus siro Linnæus, 1758, and *Aleurobis farinæ* de Geer are believed to be the cause of vanillismus.

Glyciphagus prunorum Hermann is the cause of 'grocer's itch.'

Rhizoglyphus parasiticus Dalgetty, 1901, is the cause of a type of so-called 'coolie itch' of the feet. Bell states that it causes a large circular superficial sore on the sole of the foot. 'This is produced by numbers of the parasite invading the skin.

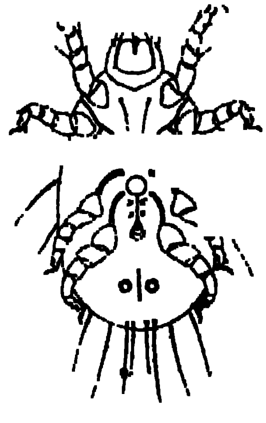

FIG. 869.—*Rhizoglyphus parasiticus*: MALE. (After Dalgetty.)

SARCOPTIDÆ.

Sarcoptes scabiei var. *hominis* Linnæus, 1758, is the cause of scabies in man.

In addition to this common parasite, there are several varieties, usually occurring in the domestic animals, which may at times attack man—*e.g.*, *Sarcoptes scabiei* var. *canis*, found in the dog; *S. scabiei* var. *ovis* in the sheep;

S. scabiei var. *equi* in the horse; *S. scabiei* var. *suis* in the pig; *S. scabiei* var. *auchenia* in the lama; *S. scabiei* var. *cameli* in the camel.

Notœdres cati var. *cati* Hering, 1838, found in cats, may occur in man.

DEMODICIDÆ.

Demodex folliculorum Simon, 1842, is said to be the cause of certain inflammations in seborrhœa. Some authors consider them to be of importance in the carriage of certain diseases, such as leprosy and cancer.

Rarer Acarinæ, which attack man occasionally, are *Trombidium striaticeps* Heim and Oudemans, 1904, on fowls and dogs; *T. americanum* Riley and *T. irritan* ; *Metatrombidium poriceps* Heim and Oudemans, 1904, on fowls and dogs; *Microtrombidium meridionale* and *M. pusillum* Hermann.

Copra Itch.

Definition.—A very pruriginous dermatitis, found in people handling copra, and caused by *Tyroglyphus longior* Gervais var. *castellanii* Hirst (p. 729).

Historical and Geographical.—This dermatitis was described by Castellani in 1911, who observed it in Ceylon in people handling copra, and considered it to be due to an acarus-like parasite, swarming in many samples of copra. He sent the specimens of the parasite to Hirst, who described it as a new variety of *Tyroglyphus*—*Tyroglyphus longior* Gervais var. *castellanii* Hirst.

Castellani's researches have been recently confirmed by Graham Little, Whitfield and Ditlevsen.

Ætiology. — The mite is present in huge numbers in certain samples of copra, and may occasionally be found on the skin of the patients, but remains on the skin only temporarily, as it does not bury itself. It apparently induces the dermatitis in the same manner as *Pediculoides ventricosus* Neuport, which lives in diseased cereals, produces an eruption in persons handling such cereals.

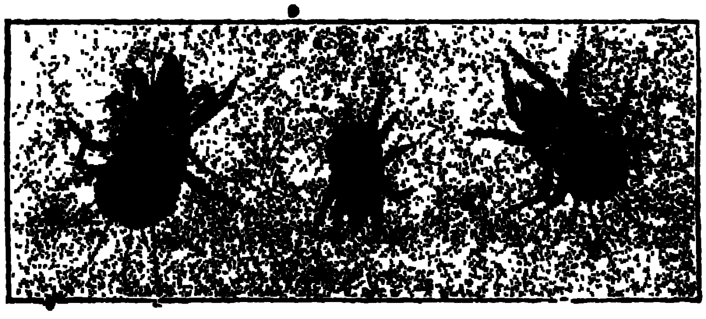

FIG. 870.—MICROPHOTOGRAPH OF THE TYROGLYPHUS OF COPRA ITCH. (×40.)

Experimental Reproduction.—When copra dust containing the mite is rubbed into the skin, itching frequently begins very shortly after, and twenty-four to forty-eight hours later an extremely pruriginous urticarial or papuloid eruption often develops. The same result is obtained by picking the mites out of copra dust and placing them (alone, without any dust) on the skin under a covering, such as a piece of lint kept in place by a bandage. The pustular stage did not occur, but this being due to scratching and secondary pyogenic infections, there was no time for it to develop, all the people refusing to go on with the experiment after the second day. Some individuals seem to be unaffected by the presence of the mite or the copra dust containing it.

Symptomatology.—The hands, arms, legs, and sometimes the whole body except the face, present fairly numerous, very pruriginous papules, often covered by small, bloody crusts due to scratching; papulo-pustules and pustules are also generally present. The eruption has no tendency to spontaneous cure while the patient goes on working in the infected mills.

Diagnosis.—On superficial examination the condition may be easily mistaken for scabies, but burrows are not present and the two parasites are very different.

Treatment.—The best treatment is the daily application of β-naphthol ointment (5 to 10 per cent.). The action in these cases cannot be compared to what takes place in scabies, because in copra itch the acarus-like parasite remains for only a short time on the body, and in most cases when the ointment is applied at night the mites are no longer there. It may act as an antipruritic antiseptic, and in this way diminish scratching and secondary pyogenic infections. It is probable also that a small amount of the ointment may remain on the skin after the morning bath and be repellent to the mite, in this way preventing the daily reinfection which otherwise takes place.

Grain Itch.

Synonyms.—Straw itch, Barley itch, Dermatitis Schambergi, Urticarioid Dermatitis, Dermatitis Ditropenotus, Aureoveridis, Acara Dermatitis urticarioides, Schamberg's disease, Straw-mattress disease, Cotton-seed Dermatitis.

Definition.—Grain itch is a dermatosis caused by *Pediculoides ventricosus* Neuport, 1850 (*vide* Figs. 343-345, p. 728).

History.—During the last fifty to sixty years this disease has been recognized in Europe, but only since 1901 in America, when Schamberg described it. In 1909, Goldberger and Schamberg found that it was caused by the same mite as in Europe. Since 1914, when Willcock drew attention to the matter, it has been well known to be present in cotton seed infested with the pink bollworm, of which it is a parasite, and from which it has passed to man to Egypt and England.

Climatology.—It is found in Algeria, where it is common, and in other parts of Northern Africa, in Italy, and it is said to occur in India. Cases have also been recorded from France, England, Austria, and Germany. In France there was an epidemic as long ago as 1850 in Bordeaux. In 1867 some cases were found in the department of Indre and in 1872 in the Canton of Creon.

Ætiology.—The disease is caused by *Pediculoides ventricosus* Neuport, which usually feeds upon the wheat-straw worm (*Isosoma grande* Riley), the joint worm (*Issoma tritici* Fitch), the Angoumois grain moth (*Sitotropa cerealella*) and the caterpillars of the cotton moth (*Gelechia gossypiella*). The mite attacks people; it attaches itself to the skin by its sucking discs and claws, and probably injects some irritaing substance into the skin while attempting to obtain nourishment.

Symptomatology.—The mite causes an urticarial and papuloid eruption on the breast, arms, face, neck, and shoulders of persons handling corn and barley, or cotton seed, which has no tendency to spontaneous cure while the people continue to handle the infected grain. The symptoms begin after an incubation of twelve to sixteen hours with itching and the appearance of wheals surmounted by vesicles, which are usually about the size of a pin's head. These vesicles may at times pustules in a few hours. Severe cases show febrile symptoms, vomiting, and albuminuria.

Diagnosis.—The presence of an eruption somewhat resembling lichen urticatus in people handling grain or straw or cotton seed, or sleeping on new straw mattresses, should always arouse suspicion of the presence of this mite, and search for it should be made in the grain or straw or cotton seed.

Treatment.—The treatment consists in removal of the cause—*i.e.*, of handling the infected grain—and the application of soothing lotions, such as calamine lotion, or a dilute carbolic acid or acetic acid lotion.

Scabies.

Synonyms.—Scabrities, Psora (term wrongly applied), Itch, Courap (=itch Bontius), Scabies indica (Sauvages), La gale (French), Kraetze (German), Sarna (Madeira), Scabbia (Italian).

Definition.—Scabies is an infection of the superficial layers of the skin by the female of *Sarcoptes scabiei* var. *hominis* (Linnæus, 1758), which, making a minute opening into the horny layer, forms a burrow more or less parallel to the surface, and in so doing causing itching. Secondary lesions are vesicles (of which the most typical is at the far end of the burrow, immediately beyond which lies the acarus), scratches, scabs, pustules, and a superficial dermatitis.

History.—Aristotle appears to have known the itch insect, but if this is true the knowledge was lost, and certainly Avenzoor in the twelfth century deserves the credit for discovering or rediscovering it. Scaliger, in 1557, described it as being globular in form and so minute as to be scarcely perceptible. He says that the people of Turin called it *scirro*, while in Gascony it was known as *brigant*. He also described the burrows, and in 'Exercitatio 194, de Subtilibus,' numero 7, he states that when extracted it shows a certain amount of movement, and when crushed between the nails causes a slight noise and emits a little fluid. After this it was described by Ingrassius of Naples, by Gabucinus, by Jobertus, by Aldrovandus, but more especially by Mouffet in his 'Insectorum,' completed in 1589. In 1654 Hauptmann, who called the acari 'Reitleisen,' published the first figure of the mite in 1654 and again in 1657. He was followed by Haffenreffer in 1660, by Heintke in 1675, who gave extraordinary illustrations of the arachnid, and by Ettmuller in 1682, whose illustrations are recognizable. In 1683 Bonomo and Cestoni published their letter to Redi on the subject, and in 1702 this communication was read by Mead before the Royal Society, and published in the Philosophical Transactions. Bonomo described and figured the egg. He was followed by Morgagni in his fifty-fifth letter, Book IV., by Bonanni in 1691; by Linnæus in 1767, who named it *Acarus* in his 'Systema Naturæ,' calling it *Acarus exulcerans*, but earlier in 'Entomologia Faunæ Suecicæ' he termed it *Acarus humanus subcutaneus*, and in the thirteenth edition of the 'Systema,' 1788, *Acarus siro* is separated from *Acarus scabiei*. It was described by Schaeffer in 1766, by De Geer in 1778, by Fabricius in 1780, by O. F. Müller in 1776, and by Latreille as *Sarcoptes hominis*; by Baker in 1744, by Casal in 1762, by Wichman in 1786, and by Adams in 1905. Adams says that in Madeira there is a disease due to ouçoes which is not itch, being associated with fever, but is due to a small animalcule. Excluding the observations (*sic*) of Galés we next come to Gras' pamphlet which appeared in 1834, and to Raspail's work which was also published in the same year, and which established firmly the belief in the arachnid.

In 1861 Fuerstenberg wrote a monumental work on the subject entitled 'De Kratzmilben der Menschen und Thiere.' Finally, in 1915, Charles Singer wrote an interesting history of the small animalcule. Notwithstanding all this scientific work, the dermatologists were for long sceptical as to the causal action of the small parasite—*e.g.*, Bateman—but Erasmus Wilson, in 1842, was quite clear on this point.

Climatology.—Scabies is known all over the world, and has local names in all localities. It is very common in the tropics, and is more frequently met with in the low country than in the hills.

Ætiology.—The causal agent is the mite *Sarcoptes scabiei* var. *hominis* (Linnæus, 1758), which lives on the surface of the skin, but after impregnation the female burrows into the epidermis, making a little orifice marked by slight fraying of the horny layer. From this orifice it slowly works its way more or less parallel to the skin, but penetrating deeper and deeper. In so doing it deposits fæces and eggs along the burrow, while the mite itself lies buried in the horny layer at the far end of the burrow and just beyond a small vesicle, which often marks its position. It may be obtained by opening the burrow by means of a fine needle until it reaches the grey speck which marks the mite, which can then be extracted. The female finally dies in the burrow, and the males are believed to expire after copulation, but the species is kept in existence by the eggs, which produce six-legged larvæ in some four to eight days. These moult several times, and then become the eight-legged nymph, without fully developed sexual organs, which finally becomes the sexually mature mite. The adult female is 330-450 microns in length, but the male is smaller.

More rarely 'scabies' may be caused by the mite belonging to an animal, but the infection in this instance does not last long.

The vesicles and the irritation are thought to be caused by excretions from the mite.

Infection generally takes place by contact, and hence is more common among the poor, who are crowded together, whereas in the better classes it usually begins about the generative organs, and is usually thought to be spread by sexual intercourse.

Symptomatology.—The primary symptom is itching, especially when warm and when in bed, while the first clinical sign is a small line on the surface of the skin, and which may be reddish. If this line is carefully examined with a lens the orifice of entry may be found as well as a minute vesicle at the farther end, but this may be absent. Just beyond the end of the burrow a small body of greyish glittering appearance may be seen in the depth of the epidermis if examined by means of a lens. This body is the mite.

In addition to these primary lesions secondary signs may be visible in the form of scratches, papules, pustules, and even eczematous patches.

The primary sites are between the fingers, the wrists, the ulnar side of the hands, the elbows, the front of the armpits, the nipples, the umbilicus, the penis, the gluteal regions, and between the toes.

In the tropics in cleanly people it is often confined to the scrotum.

Diagnosis.—The characteristic signs are the burrows and the distribution of the eruption, while the basis of the diagnosis is the discovery of the mite.

Treatment.—Order the patient to take a hot bath and to scrub himself all over with soap and water, and then to rub all over the body sulphur ointment of the British Pharmacopœia from the margin of the hairy scalp to the soles of the feet. Next day only the face is washed, and that night more ointment is rubbed in, and the same treatment is applied another night. Then on the fourth a hot bath is taken and all the clothing and bed linen changed, the old underclothing and bed linen being disinfected by being placed in boiling water.

This usually cures the eruption, but a recurrence may occur in about a week if any ova have survived, and may require a repetition of the treatment.

The sulphur ointment may cause a slight dermatitis with itching, which may be mistaken for a recurrence of the affection. In order to cover the odour of the sulphur a few drops of oil of lavender may be added.

Prophylaxis.—Every person suffering from itch should be carefully and promptly treated in order to avoid epidemics.

The horse, sheep, dog, cat, wolf, fox, pig, poultry, and many other animals, suffer from scabietic conditions due to mites more or less closely allied to the *Sarcoptes scabiei* of man. These mites may occasionally be transferred to man, and induce a dermatitis which clinically may resemble scabies, though as a rule much less severe.

IV. NEMATODE DERMATOSES.

Several species of the Nematode cause dermatoses—*e.g.*, *Rhabditis niellyi* Blanchard, 1885 (p. 627), *Strongyloides stercoralis* Bavay, 1876 (p. 628), *Filaria bancrofti* Cobbold, 1877 (p. 633), *Onchocerca volvulus* Leuckart, 1893 (p. 649), *Loa loa* Guyot, 1778 (p. 645), *Agamofilaria georgiana* Stiles, 1906 (p. 642), *Ancylostoma duodenale* Dubini, 1843 (p. 666), and *Necator americanus* Stiles, 1902 (p. 673).

The most important of these is the dermatitis caused by the two last-named worms. This dermatosis is described under the heading Ankylostomiasis on p. 1764.

V. CESTODE DERMATOSES.

The cestode dermatoses are usually due to *Sparganum prolifer* Ijima, 1905 (p. 606), which produces nodules in the skin, which are associated with considerable swelling, thus giving rise to an appearance not unlike elephantiasis. In addition, there may be an acne-like eruption all over the body, which is very irritable and causes pruritus. On scratching the papules and producing excoriations the worms may escape, while on incising a nodule a cyst, with one or two worms embedded in slimy jelly, or a watery fluid, may be found.

After lasting for some weeks or months the cyst walls become firm and thick, and so encapsulate the worms. The condition may last for years. There is no known treatment.

CHAPTER XCVII

DYSIDROSES AND DYSTROPHIES

Hyperidrosis—Bromidrosis—Chromidrosis, etc.—Dysidroses: Prickly heat—Cheiropompholyx—Dysidrosis exfoliativa—Dystrophies: Leucoderma—Albinism—Melung—Chloasma bronzinum—Dermatosis festonata frontalis—Dermatosis nigro-circinata—Ochrodermatosis—Melanonychia—Xanthoderma areatum—Mongolian spots—Tattooing—Ainhum—Symmetrical palmar erythema—Acrodermatitis vesiculosa—References.

HYPERIDROSIS.

Remarks.—This condition, as well as bromidrosis, is a cosmopolitan one, but for climatic reasons both are so common and important in the tropics that a short account of them is given in this chapter.

Synonyms.—Idiopathic hyperidrosis, Idrosis, Polyidrosis. Ephidrosis Sudatoria.

Symptomatology.—Excessive perspiration may be generalized or localized. In the latter case it is generally symmetrical, the regions most frequently affected being the axillary regions, hands, feet, and genital regions. Other regions may be affected. In one of our native assistants during the hot season there is an extremely severe localized hyperidrosis of the anterior region of the neck, the sweat falling down continually in large drops.

Symptomatic Hyperidrosis.—This occurs in many tropical diseases, especially in malaria, Malta fever, etc. Localized one-sided hyperidrosis has been observed by us in some cases of framboesia.

Prognosis.—In the idiopathic type the prognosis is good, the condition disappearing when the hot season is over, but it is often associated with prickly heat.

Treatment.—For the general hyperidrosis common during the hot season we are not in favour of any drastic internal treatment such as the administration of belladonna. In fact, we think it may be dangerous to stop suddenly this hyperidrosis, which is in reality merely a physiological fact. For such cases we simply recommend using some potassium permanganate, or cyllin, or a little menthol alcoholic solution in the daily bath, and dusting of the body with any simple antiseptic powder, such as zinc oxide, starch, and boric acid in equal parts (see Prickly Heat, p. 2224).

In really severe cases of generalized hyperidrosis, belladonna or atropin may be administered; but they stop the secretion only for a time, and must be pushed till unpleasant symptoms appear. Sulphur and acid drinks have little effect, but they are harmless. Sulphur is occasionally given by us in cachets (3 grains) three times daily after meals.

In localized hyperidrosis the treatment varies according to the parts being non-excoriated or excoriated. In patients not presenting excoriations, naphthol or salicylic or formalin-alcoholic lotions (1 per cent.), followed by a salicylic, boric, or tannoform powder, are very useful. If there are excoriations or inflammatory signs, no alcoholic lotions should be used, but merely water solutions of boric acid (2 per cent.), carbolic (1 per cent.), permanganate of potassium (1 in 4,000), and occasionally hydrogen perchloride (1 in 2,000 to 1 in 4,000), after which a salicylic or boric powder is applied. It should be always remembered to sprinkle with the same powder the socks, shoes, and undergarments.

BROMIDROSIS.

This term is used to denote offensive sweating.

Ætiology.—The bad odour seems to be due to the growth of various bacteria, as observed by Thin, and is due not only to the sweat, but also, and probably in a higher degree, to the sebaceous secretion. The condition is very common in native races—negroes, Indians, and Chinamen; most natives seem to have it to some extent, in fact. On the other hand, however, it is to be noted that certain natives state that they can detect in almost every European a special, disagreeable odour. Certain authorities are of opinion that each race has a recognizable different odour.

Symptomatology.—As a rule, when the sweat has an offensive odour, there is also hyperidrosis, but in certain cases the quantity of sweat is not more than usual. The condition is usually localized, occasionally general. The situation of bromidrosis is, in order of frequency, the feet, the axillary regions, the perineum, and genital organs. When the condition affects the feet—the commonest localization—the odour is most offensive, and has been compared to that of putrid cheese. When it affects the axillary regions, the odour is offensive, but as a rule is of a different character.

Symptomatic bromidrosis has been described in pinta, in certain cases of Madura foot, in acanthosis nigricans, after eating certain foods, etc.

In contrast to bromidrosis, cases have been described of certain individuals having a pleasing smelling sweat, with the odour of violets or musk. There is a tradition that certain saints exhaled a pleasant odour.

Prognosis.—Except in those cases when the bad smell is due to accumulated dirt—when a thorough washing with carbolic soap will cure the condition—bromidrosis is not of easy cure, but the bad smell may be hidden in various ways.

Treatment.—This is the same as for hyperidrosis, but formalin lotions (½ to 3 per cent.), alcoholic or watery, are especially useful, Lysoform (2 to 5 per cent.) is efficacious. Afterwards a powder such as ac. salicyl. gr. x., talci ℥i., or ac. borici ʒi., talci ℥i., should be used, and some boric acid should be sprinkled in the socks and also in the boots. If there are excoriations, formalin should not be used, but instead hydrogen peroxide (10 per cent.) or potassium permanganate (1 in 4,000), followed by boric powder or a dermatol, xeroform, or tannoform powder (ʒi. of any of these drugs to ℥i. of talci). Internal treatment is not of much use, but sulphur (gr. iii.) three times daily may be tried. One of us had good results in a case by the administration of urotropin, gr. x., thrice daily.

Chromidrosis.

The term is applied to coloured excretion of sweat or sebum. The condition affects in most cases the armpits, but cases have been described affecting the face, chest, abdomen, inguinal regions, hands, and feet. The colour has been described as black, blue, red, green, yellow, and violet. We have personally observed only two cases of chromidrosis. In both the axillary regions were affected, the colour was brick-red, and the sweat stained the clothes red. In one of the cases it was due to *B. prodigiosus*, in the other to a red pigment-producing coccus.

Phosphoridrosis.

Synonym.—Phosphorescent sweat.

This condition has been described by Kostor and others, but is very rare. In one case it was stated that it appeared after eating phosphorescent fish. According to Beyerink the phosphorescence is due to photo-bacteria.

Uridrosis.

Small white crystals, forming a sort of hoar-frost, are present on the skin, due to excretion by the skin of urinary constituents, especially urea and chlorides. Nash records several cases of a whitish deposit on the skin in native children and natives, which, according to some authorities, may have been the same condition.

Hæmatidrosis.

Several cases of hyperidrosis with red blood cells and leucocytes in the sweat have been placed on record.

Anidrosis.

Idiopathic total anidrosis, or absence of sweat, is exceedingly rare, but a diminution in the secretion of sweat is often observed. There are people in whom the bringing about of perspiration by hot-air baths and drugs is very difficult.

Symptomatic anidrosis is present in leprotic patches, and may be of diagnostic value. It is seen also in scleroderma, general or circumscribed (morphœa), and in xeroderma. The secretion of sweat may be much decreased in diabetes and certain nervous conditions.

DYSIDROSES.

Prickly Heat.

Synonyms.—Lichen Tropicus, Sudamina Papulosa, Miliaria Rubra, Miliaria Papulosa, Salpullido (Cuba), Calor Picante (Minorca), Humon El-Nil (Arabic).

Definition.—Prickly heat is a papular or papulo-vesicular eruption, with marked pruritus, and associated with profuse sweating.

Geographical Distribution.—The condition is found all over the tropics and subtropics. It may be observed also in temperate zones during the hot season, especially at sea-bathing places.

History.—Bontius described the affection in his work, 'De Medicina Indorum'; Cleghorn in his book, 'Diseases of Minorca,' identifies it with sudamina; he states that the term used in Minorca to indicate the eruption was *calor picante*. Willan, Johnson (1821) and other English observers described it in India and other tropical countries with the term *Lichen tropicus*. Armand in 1854 describes it in his book, 'L'Algérie Médicale,' using the name *Lichen miliar pruriginosus;* he mentions that sea-bathing often increases the severity of the eruption. Mestre, in Cuba in 1862, wrote a very complete paper on the condition; he uses the term 'salpullido.' In more recent times the eruption has been studied by Robinson, Török, Durham, and many others.

Ætiology and Pathology.—Politzer considers the disease to be due to the obstruction of the flow of sweat brought about by the cells of the epidermis swelling by imbibition from the excessive sweat. Pearse considers it to be due to an acute distension of the sebaceous glands by their own secretion. Robinson states that the inflammation is about the sweat-pore, while, according to Török, it has nothing to do with it. In our experience, the inflammation is not always about the sweat-pore.

Durham believes prickly heat to be an infective disease, caused by a minute actively motile amœba; his results, however, have not been confirmed.

Symptomatology.—This affection is extremely common in tropical countries, especially in new arrivals. The eruption consists of small pin-head papules, which may enlarge to the size of a millet-seed, and even larger. The papules are generally conical, angry red, and often occupy the orifices of the sudoriferous follicles; they are occasionally topped by a small vesicle, the contents of which may later, occasionally, become purulent. Besides the papules, roseola-like spots are often seen; these in some cases may coalesce and form large erythematous patches. Occasionally minute glass-like vesicles of sudamina crystallina are also present. The eruption is found on the parts of the body where the patient perspires most. It is very commonly observed round the waist, the back, chest, arms, and forehead; it may extend to the whole surface of the body, except, it is generally stated, the palms and soles. In our experience, when the eruption is general, the palms and soles also may be affected; in such situations, however, no papules are found, but only roseola-like spots. We would also call attention to another feature found in cases of acute severe general prickly heat eruption: in several such cases the oral mucosa and the fauces will appear acutely congested. The congestion subsides on the disappearance of the cutaneous lesions.

Diagnosis.—This is generally easy; from eczema it is distinguished by the greatly increased flow of perspiration, and by the absence of any moist lesions during the whole course of the malady. Our experience is, however, that in some cases true eczema—especially of the papular type—develops on prickly heat lesions. In cases of generalized prickly heat, with roseola-like spots on the palms and soles, acute patchy congestion in the oral mucosa and pharynx, a syphilide must be excluded, for several of our patients believed themselves to be affected with syphilis; but the extreme pruritus is generally sufficient to exclude it.

Prognosis.—As a rule, the prognosis is good, the eruption disappearing quickly under proper treatment. The patient, however, complains of the severe itching, which often keeps him awake at night. In some few cases no treatment is of any avail, and the patient must be sent up to the hills; in others, crops of boils develop, or pyosis mansoni or impetigo contagiosa may supervene, especially in children.

Treatment.—The patient must be kept cool; he should not take much to drink, and should abstain from drinking hot tea. Too warm clothing should be avoided; flannel and woollen things often make prickly heat worse. In such cases silk underclothing may be recommended, but not in people liable to abdominal chills. All underclothing must be changed at least once daily and after taking any violent exercise. Sea-bathing is injurious. The treatment which in our experience has answered best is the free use, several times daily, of a salicylic alcoholic lotion (ac. salicyl. ʒi., spir. rect. ℥viii.), followed by the general application of a salicylic or boracic or camphor powder, such as ac. salicyl. gr. x., talci ℥i., or ac. borici ʒi, talci ven. ℥i., or camphor gr. xxxv., zinci ox. amyli āā ℥ss. It is better, as a rule, to avoid greasy preparations.

After the eruption is cured the patient should be directed to use some Condy's fluid, cyllin, or other disinfectant in the bath, and afterwards to apply one of the powders mentioned above.

The so-called 'Castellani's lotion' much used in the East, consists of menthol gr. x., ac. salicyl gr. ii., zinci ox ʒvi., calaminae ʒiii., spirit. rect. ℥ii., glycerin. ʒi., aq. rosae ad ℥vi. It should be diluted with the same amount of water when applied to the face or when used for children.

Cheiropompholyx.

Synonyms.—Dysidrosis, Pompholyx.

This affection is seen in the tropics, and is also met with in temperate zones during the hot season. To Tilbury Fox and J. Hutchinson belongs the merit of having separated this affection from eczema.

Ætiology and Histopathology.—Tilbury Fox believed the disease to be due to accumulation of sweat induced by the blocking of the pores of the sudoriparous glands. The more recent researches of Unna, Norman Walker, Williams, and others show that the lesions are of an inflammatory character; the vesicles are found in the prickly layer, and often press to one side of the sweat channel.

Unna described a bacillus as the cause of the disease. Some authorities consider the condition to be of neurotic origin.

Symptomatology.—The eruption is found in individuals who suffer from hyperidrosis. It is characterized by the presence of deeply seated translucent or opalescent, sago-like vesicles between the fingers and toes; the vesicles are not, as a rule, surrounded by an inflammatory halo; they very rarely coalesce, and usually do not break, but dry up gradually, being thrown off with the exfoliating epidermis. The vesicles in many cases are few in number; in others they may be numerous, and the eruption may extend to the palms, backs of the hands, and occasionally the arms. There is unbearable pruritus, and in some cases, owing to the scratching, an eczematous dermatitis may develop, especially between the toes.

Diagnosis.—Some authorities still maintain that cheiropompholyx is merely eczema. In our experience, the disease must be separated from eczema, the principal characters of differentiation being the deep situation of the vesicles, the fact that they very rarely rupture, and that, as a rule, they are not surrounded by an inflammatory zone; moreover, the parts affected are generally bathed in sweat.

Prognosis.—The disease is not a serious one, and, under proper treatment, the eruption heals; but the tendency to recur is great.

Treatment.—When the vesicles are few in number, pricking them with a sterile needle, washing them with a perchloride lotion (1 in 2,000), followed by the application of a 1 to 2 per cent. naphthol ointment, gives much relief. When the vesicles are numerous, and the eruption has spread to the backs of the hands and arms, calamine lotion, to which a little menthol and alcohol has been added, answers well, or a salicylic alcoholic lotion (ac. salicyl. ʒi., alcohol rect. ℥iv., aq. ad ℥viii.) may be used.

Dysidrosis exfoliativa.

This affection, described by Castellani, is closely related to cheiropompholyx. The affected parts—generally the palms of the hands—are bathed in continuous perspiration, and large flakes of epidermis exfoliate. In most cases no cheiropompholyx-like vesicles are found; in fact, no vesicles of any type can be detected. The affection becomes cured spontaneously on the patient going to the hills or during the cold season, but it is apt to recur.

Bathing the affected parts with a resorcin lotion (½ per cent.) at first, and later, when the desquamation has ceased, the application of calamine lotion, is useful.

Sweat Desquamation.

Schornberg has applied the term '*sweat desquamation*' to the minute whitish scales, often arranged in rings, and found on the palms of persons who perspire profusely. The condition may occasionally be confused with a syphilide, from which it is differentiated by the absence of other syphilitic signs, such as enlargement of the lymphatic glands, etc., and by the fact that it disappears on the patient going to the hills.

DYSTROPHIES.

Leucoderma.

Synonyms.—Leucopathia, Vitiligo, Acquired leucopathia, Acquired leukasmus, Acquired achromia, Acquired piebald skin, Maladie de dépigmentation (O'Zoux).

Leucoderma is much more common in tropical countries than in temperate zones. The natives of Ceylon and India have a dread of developing leucoderma, and look upon it as a loathsome disease.

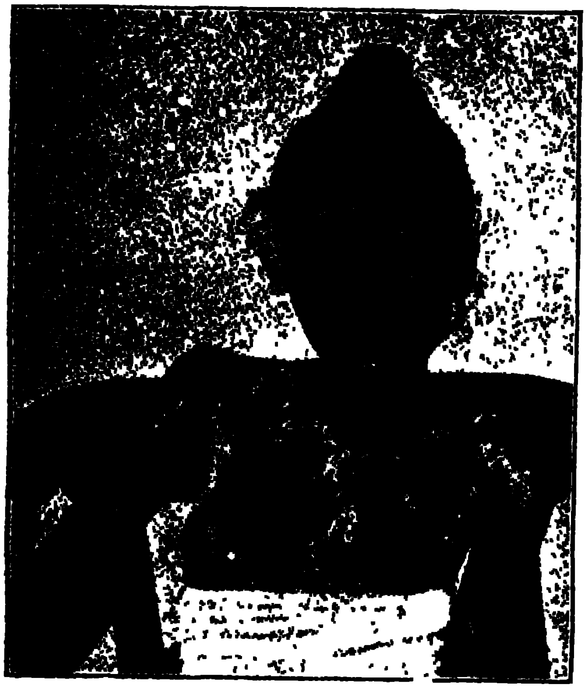

FIG. 871.—LEUCODERMA IN A SINHALESE WOMAN.

Ætiology and Pathology.—The ætiology is unknown. It is generally considered to be a trophoneurosis. Occasionally there is evidence of hereditary influences, several members of the same family being affected. The malady may start without any apparent cause, or in some cases may begin after an injury, after a burn, after too strong a caustication. In fact, the application of strong remedies should be used with care in natives. We have seen leucoderma patches appearing after the application of pure formalin. Patches of leucoderma may develop also in chronic epiphytic skin diseases, the fungi apparently having a deeply disturbing effect on the pigment formation.

FIG. 872.—LEUCODERMA OF THE HANDS AND ARMS.

Symptomatology.—Leucoderma is characterized by the presence of non-pigmented areas, white, ivory-like, or pinkish. The patches are roundish or oval, with a smooth surface; they slowly enlarge and coalesce, giving rise to large, irregularly outlined areas. Occasionally almost the whole body becomes affected; more often it is the face and hands which are affected, and there may be a certain symmetry. The initial patches are often surrounded by a zone of hyperpigmentation. Occasionally within the white areas small dot-like zones of pigmentation are left. The hairs of the affected parts frequently become white, but sometimes remain of normal colour. The white patches do not show any marked change in sensation; there is never anæsthesia; in many cases there is hyperæsthesia to heat and light stimulation. The texture of the skin remains normal; occasionally slight atrophic processes may be noted. It is usually stated that the general health is not impaired. In our experience, however, when the patches are large and situated on uncovered parts of the body, especially the face, symptoms of severe asthenia have been noticed. Moreover, the patients complain that they cannot do any work in the sun, as they experience a burning sensation in the white patches, and they suffer from giddiness.

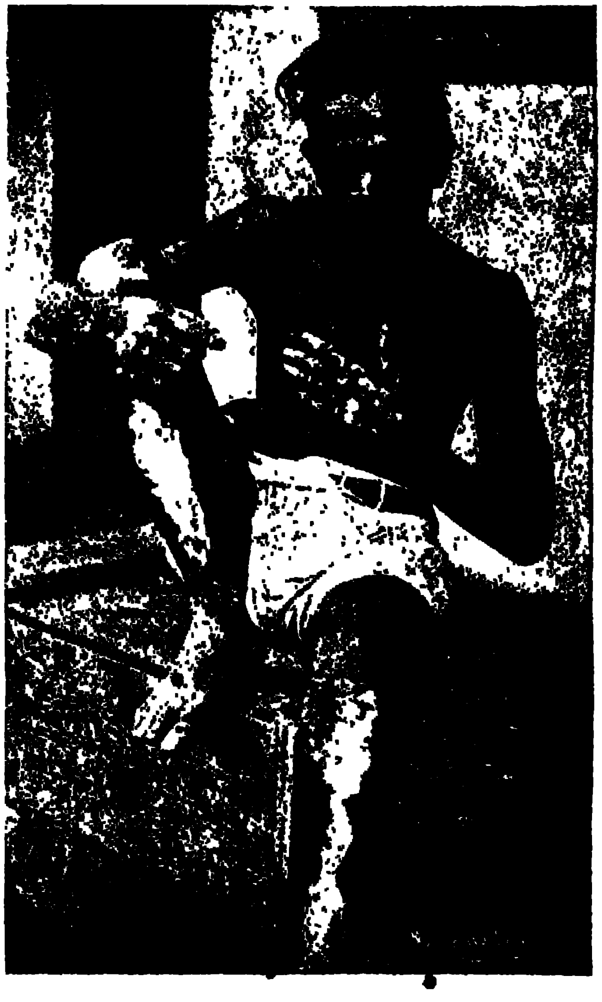

FIG. 873.—LEUCODERMA IN A SINHALESE.

Clinical Varieties—*Melung* (*Beta*).—This type of leucoderma was first described by Ziemann, and is fairly common among West African negroes. It is found also in Ceylon, India, and Burma, in the last-mentioned country having been described by Castor. The affection is always symmetric, and attacks only the palms or the soles, or both palms and soles. Small areas of the skin undergo a slow process of depigmentation, becoming whitish or yellowish; there is no alteration of sensibility. The depigmented areas, which are generally of various shape, are intermixed with patches of normally pigmented skin, so that the palms and soles present a marmoriform appearance.

The disease is chronic and incurable. It often develops in childhood, and several members of the same family may be affected.[1]

A variety of leucoderma in the shape of two small, often triangular spots, one at each angle of the mouth, has been observed by Pusey in a Burmese girl and by one of us in Ceylon. The mucosa of the lips may also show leucodermic patches.

Diagnosis.—The diagnosis is generally easy. The patches, in contrast to leprosy, do not show anæsthesia; from *morphœa* it is distinguished by the absence of any abnormality in the texture of the skin; from tinea flava, tinea alba, and pinta, by the absence of any fungus.

Prognosis.—The disease may be said to be incurable. When large patches are present, the patient complains often of asthenia, and may become unfit for work, especially work in the open air and sun.

Treatment.—The disease is generally incurable, but the spreading of the patches may be prevented, and occasionally a slight improvement may be brought about, in our experience, by an energetic arsenical treatment. We generally give arsenious acid in a pill (gr. $\frac{1}{50}$) three to six times a day, or atoxyl injections (5 grains every other day). Gillmore has tried soamin with fairly good results. We have seen no benefit from the administration of suprarenal extract, as recommended by several authors. The white colour may be partially hidden by applying a lotion of nitrate of silver or potassium permanganate, or by tattooing.

Heidingsfelt has devised an instrument consisting of a group of ten needles, which are put in movement by electrical power. In this way tattooing may be performed much more rapidly than by hand.

Sommer claims to have cured several cases of leucoderma by injections of adrenalin.

Albinism.

Synonyms.—Congenital leucoderma, Congenital leukopathia, Congenital achromia, Congenital leukasmus.

The affection is found in the tropics more frequently than in temperate zones. It is characterized by congenital absence of pigment in the skin, hair, iris, and choroid. There are cases, however, of partial albinism in which only the skin is affected. The skin has a milky-white or pinkish appearance; the iris is rose-coloured, and the pupil red. There is intolerance to light; hence the pupils will be generally found to be contracted, and the patient, to avoid the strong light stimulus, may go about with the head downwards. Nystagmus is observed in several cases. The hair is generally white or yellowish-white, fine and silky. We have seen albinos with red hair. Albinos are generally poorly built, weak and feeble individuals.

Ætiology and Pathology.—The ætiology is unknown. The affection is more often observed among coloured races than in the white races. It shows a certain family tendency. It is said that cases occur more frequently in the offsprings of consanguineous marriages. The histological examination of the skin shows absence of pigment as the only abnormality.

Treatment.—The affection is incurable.

Erythema Solare.

The effects of sunlight on the skin, including the histology of the lesions, have already been discussed in Chapter III., pp. 83–85. They are caused by the active effects of the rays at the violet end of the spectrum. The skin of the parts exposed becomes erythematous, swollen, and vesicles and bullæ may appear. Desquamation follows, and the skin is often left pigmented (sunburn).

The treatment consists in applying calamine lotion, and later any bland ointment such as simple cold cream.

Dermatitis Solaris.

After repeated attacks of erythema solare—or at times without any history of such—the skin of the hands and exposed parts in planters and other people living an outdoor life in the tropics becomes slowly reddened, and may be slightly rough to the touch. Freckles and hyperpigmented spots are generally present, and not rarely small telangiectasia. In a later stage warty patches often appear, and the dermatitis, as noted by McLeod, may somewhat resemble the dermatitis produced by X rays. Atrophic changes may also develop. The condition, which is also known by the term *tropical skin*, is somewhat similar to what Unna called 'seaman's skin' and to senile atrophoderma or biotripsis (see p. 2282).

Diagnosis.—The diagnosis from pellagra has already been discussed (see p. 1730).

Prognosis.—The dermatitis is very obstinate, but generally becomes cured spontaneously in a cold climate.

Treatment.—A change to a temperate climate is the only efficacious treatment. Exposure to the sun is to be avoided as much as possible.

Chloasma.

Chloasma, which, as is well known, is characterized by the presence of dark brownish or dirty yellowish patches, situated commonly on the face, is of frequent occurrence in the tropics in Europeans as well as natives. The patches are plainly distinguishable in the skin of Indian and Sinhalese natives, though in African negroes they may be indistinguishable. The condition may be due to several causes, and the following types may be mentioned:—

1. **Chloasma solare (melasma solare)**, due to exposure to the sun. A similar condition may be due to exposure to a powerful light or glare of any kind, and may even occasionally develop in people who pass a long time on glaciers and fields of snow. Chloasma solare is found among Europeans, half-castes, and also in natives. In natives who wear clothes it is easy to see that the parts exposed to the sun are darker. The condition is generally found on the face, and it may be diffuse, or one or two small patches only may be present. The colour varies from a slight yellowish-brownish

to a deep black bronzine one (see Chloasma Bronzinum). On close examination it will be found that often patches of hyperpigmentation are seen side by side or alternate with patches of depigmentation of various degree, but generally slight. The patches of chloasma solare may appear quite suddenly without being preceded by erythema solare; in one of our cases they appeared on the forehead twenty-four hours after a motor-car drive in the midday sun without the hood on; in another, a European lady, who had a very delicate skin and was used to wearing gloves, very dark hyperpigmented patches appeared on the back of the hands and wrists twelve hours after exposing her hands without gloves to the midday sun. In addition to hyperpigmented spots, depigmented patches also developed.

2. **Chloasma caloricum,** from exposure to heat, or possibly the glare of fires. We have seen it several times in stokers.

3. **Chloasma traumaticum,** from mechanical irritation of any kind, scratching, etc.

4. **Chloasma toxicum,** due to irritating drugs, as, for instance, after a blister.

5. **Chloasma symptomaticum,** as, for instance, chloasma uterinum, found during pregnancy or during chronic diseases of the female genital organs. Chloasma uterinum is quite common in Sinhalese women, and is plainly distinguishable.

6. **Chloasma malaricum** and **kala-azar chloasma,** an important type of chloasma symptomaticum, is found in patients suffering from chronic malaria and kala-azar. A diffuse type of hyperpigmentation observed in chronic malaria and closely resembling Addison's disease has already been described (see p. 1180).

Hyperpigmentation may occur also in syphilis, leprosy, tuberculosis, diabetes, and many other chronic diseases.

In India a 'pigmentary fever' has been described of short duration, and said to be characterized by the appearance of hyperpigmented patches on the face (see p. 1461).

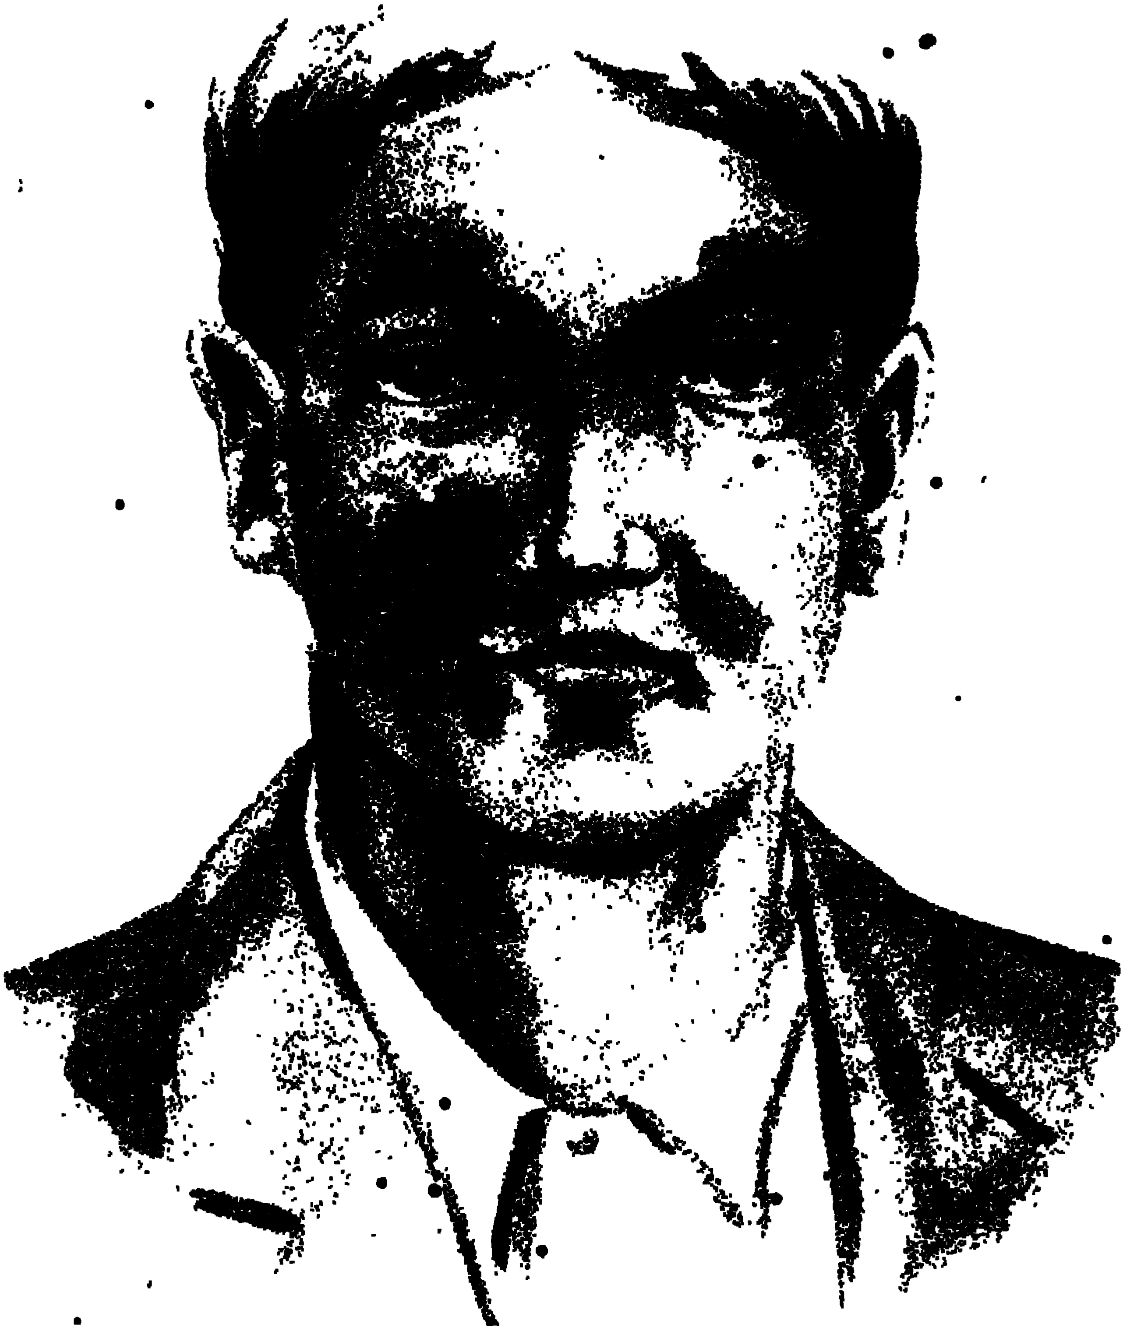
Chloasma Symmetricum.

This condition, which has been described Castellani, is often met with in Sinhalese, who greatly object to it. It is characterized by the presence of two dark brownish chloasma patches situated symmetrically one on each cheek, generally on the malar region. In some cases, in addition to these two patches, a third one is found on the nose. The colour of the patches is generally dark brownish, very rarely bronzine. The causation is unknown; it does not seem to be congenital. No treatment is of any avail.

Chloasma Bronzinum.

This somewhat rare affection is met with among natives as well as Europeans in India, Ceylon, the Malay States, China, and other

PLATE XIV.



CHLOASMA BRONZINUM.

Geo Waterston & Sons Ltd Edi

To face page 2232

tropical countries. It was first observed by Cantlie, who called it 'tropical mask,' and was later described by one of us.

Ætiology.—This is unknown, but a life in the open air with daily long exposure to a tropical sun is apparently an important predisposing cause. All our patients were European planters, or native overseers or coolies.

Symptoms.—Part of the face or the neck, or occasionally the whole face, neck, and chest, presents a peculiar pigmentation, resembling a black bronzine mask; the pigmented areas slowly but steadily increase. The disease is very chronic and incurable if the patient remains in the tropics. The general health is not impaired. The examination of the various organs is negative. The blood and urine are normal.

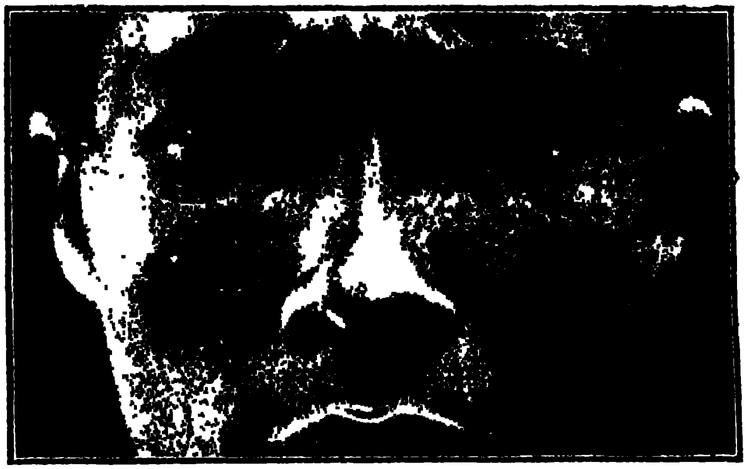


FIG. 874.—CHLOASMA SYMMETRICUM.

Diagnosis.—This is easy, even in very dark-skinned natives, the affected parts being completely black, and having a characteristic bronzine hue.

From ordinary *chloasma*, which is not rare—especially among women—the affection is easily distinguished by the bronzine tint. The absence of asthenia, loss of flesh, and diarrhœa, will suffice to distinguish chloasma bronzinum from *Addison's disease;* the history and the examination of the blood will differentiate it from malarial *pseudo-Addison's disease;* the examination of the urine will distinguish it from *diabetes bronzinum. Argyria* will be excluded by the history and by the fact that in chloasma bronzinum the mucosæ are not affected. In *ochronosis* the cartilages, ligaments, and fibrous structures become pigmented, and the discoloration is best seen about the knuckles and the tendons of the hands and feet; moreover, the urine often blackens on exposure to the air (alcaptonuria).

Prognosis and Treatment.—The disease seems to be incurable, but a long stay in a temperate zone generally improves it.

Dermatosis Festonata Frontalis.

Historical and Geographical.—This condition has been described by Castellani in Ceylon. It has recently been found also in Macedonia.

Ætiology.—This is unknown, but probably a continuous exposure to the sun and glare plays a certain rôle in the causation of the malady.

Symptomatology.—The affection, which in its severe type is rare, is found in Europeans who have resided for many years in the tropics, and who have lived an open-air life, such as planters and overseers, exposing themselves to the sun for long periods of time.

In a well-marked case (see Fig. 875) there is a festooned margin, at times slightly raised, often of a vivid bright red or coppery red colour, while the skin which it encircles has a peculiar whitish, occasionally leucoderma-like appearance, and may be slightly atrophied: at times small patches of hyperpigmentation may be present. There is very little or no pruritus, and sensation to the touch, pain, heat, and cold is not impaired.

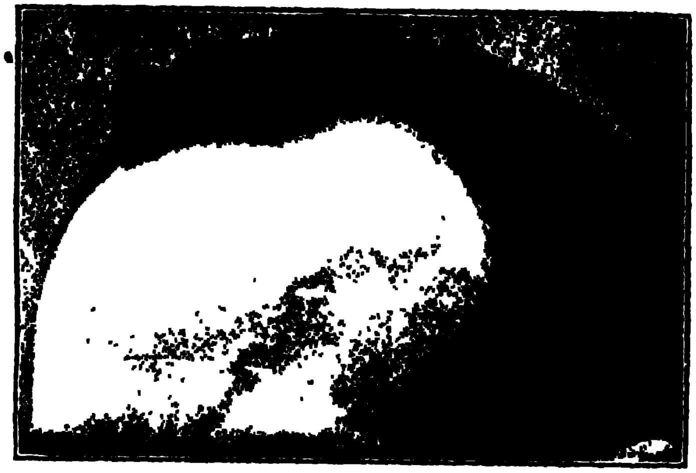

FIG. 875.—DERMATOSIS FESTONATA FRONTALIS.

The course is extremely long, the affection slowly expanding peripherally, and in a tropical climate has no tendency to spontaneous cure.

Diagnosis.—The affection is not rarely taken for a tricophytic condition, but the microscopical examination for fungi is always negative, and an antimycotic treatment does not induce any improvement. From a syphilide it is differentiated by the negative Wassermann and by the uselessness of salvarsan, potassium iodide, and mercury; from *leprosy* by the sensation being normal.

Prognosis.—The general health of the patient is not affected, but the affection runs an extremely long course, and has no tendency to spontaneous cure in the tropics. It gets much better if the patient goes to reside in a cold country.

Treatment.—The treatment is very unsatisfactory. The patient must be advised not to expose himself to the sun and glare, though it is doubtful whether the condition is directly due to such exposure. A wide-brimmed topee or sun-helmet lined with red cloth may be used.

Of the many drugs tried ichthyol seems to be the only one which at times keeps in check the condition, occasionally inducing a slight improvement. It is given internally in 5 grain doses three times daily before meals, and an ichthyol ointment or lotion (5 per cent.) may be applied to the affected skin at night, while during the day a calamine lotion may be used.

Mercury, potassium iodide, and arsenical preparations are useless.

Dermatosis Nigro-Anulata.

Historical and Geographical.—This condition has been described by Castellani in Ceylon natives and in a very dark-skinned gipsy in Macedonia.

Ætiology and Pathology.—This is unknown. It is not a frambœside, as the lesions are not influenced by salvarsan and potassium iodide; nor a syphilide, as they are not influenced by the same drugs nor by mercury; moreover, Wassermann is negative.

Symptomatology.—The condition is characterized by the presence of black, elevated, fairly hard, ring-like or elliptical multiple lesions, encircling apparently normal skin. There is no pruritus, sensation normal, Wassermann negative. The course is extremely long, lasting for years, with very little change in the aspect of the lesions

FIG. 876.—DERMATOSIS NIGRO-ANULATA.

Diagnosis.—The affection has to be distinguished from *tinea nigrocircinata* by the absence of fungi, and by the failure of any antimycotic treatment; from a circinate *frambœside* by the uselessness of potassium iodide and salvarsan; from a *syphilide* by the uselessness of the same drugs and of mercury; from *porokeratosis* by the multiplicity of the lesions.

Prognosis.—The general health is not affected, but the condition is most persistent.

Treatment.—This is very unsatisfactory. An exfoliative treatment by means of a salicylic acid ointment occasionally induces a temporary improvement.

Ochrodermatosis.

Synonym.—The yellow disease (Castellani).

Historical and Geographical.—This condition has been described by Castellani in Ceylon, in Europeans living in the low country.

Ætiology.—Unknown. The patients were not taking any drug and were not exposing themselves to the action of any toxic substance. On the strength that the condition gets much better or disappears on the patient going to the hills, a search for a possible causative organism was carried out, but with negative results.

Symptomatology.—The face, arms, hands, and at times the whole body, are of a bright yellow or saffron colour, quite different from the yellowish-greenish colour of jaundice. The scleroticæ remain completely white; the urine is of normal colour and composition; the sweat is not coloured; the stools are normally pigmented; the liver and spleen are not enlarged; and the general health is in no way affected; but naturally the patients greatly object to the disfigurement. The condition improves or disappears on the patient going to the hills or to Europe.

Diagnosis.—The bright yellow or saffron colour is different from the yellow colour generally seen in jaundice. Moreover, the scleroticæ remain white, and the urine and stools are of normal colour. The anamnesis and special analysis of urine for picric acid, etc., exclude the ordinary toxic pigmentations. The condition is distinguished from certain types of *chromidrosis*, as the sweat is not coloured and the clothes do not become stained.

In *ochronosis*, which is generally congenital, there is alcaptonuria, and the ligaments and cartilages become blackened.

In ***xanthoderma areatum*** the yellow patches remain localized to the legs, and are permanent.

Treatment.—The only successful measure seems to be to send the patients up-country. On the hypothesis that the condition might possibly be of parasitic origin, a formalin spirit lotion (1 per cent.) was prescribed is several cases, but the improvement, if any, was very slight, though certain patients stated that they thought the condition was affected in a beneficial manner by it.

Melanonychia.

Synonyms.—Black pigmentation of nails, Melanonychia falciformis.

Castellani has described in two European ladies a peculiar condition of the nails characterized by a band of black pigmentation along the free border of the nail. On superficial examination, it has the same appearance as though some dirt had accumulated beneath the free border of the nail, but on scraping this pigmentation does not disappear, and this shows that the condition is due to some pigmentation in the substance of the nail. The sufferers were in general good health, not using any internal or external

PLATE XV.

XANTHODERMA AREATUM.

[illegible] & Sons Ltd Edin.

To face page 2237

medicine which could account for the pigmentation, and the nails, apart from this line of pigmentation, appeared perfectly normal. We have, later, come across a case in a European gentleman and another case in Macedonia.

The condition slowly disappears spontaneously.

Xanthoderma Areatum.

This affection, which has been described by Castellani, is not infrequently met with among Europeans; it generally affects the lower parts of the legs; it starts very insidiously, with a yellowish or reddish-yellow spot, which is not elevated; the surface is smooth, not furfuraceous; there is no infiltration, and, apart from the colour, the affected skin is normal. There is no pruritus and no pain. The yellow spot slowly increases, and one or more other spots may appear near the first one or at a distance. Some of the spots may coalesce together, forming a large yellow-red patch of irregular or various outline. The larger patches also, apart from the colour, are normal, being of normal consistency and elasticity. The disease is very chronic. The general health is not impaired; the lymphatic glands are not enlarged, and the blood does not show any abnormality; urine normal. In all our cases syphilis could be excluded; in none was there any history of traumatism.

Diagnosis.—From chloasma, xanthoderma areatum is readily differentiated by the lighter yellow or yellowish-red, and by the different situation. The affection can be easily distinguished from xanthoma, as the texture of the skin is normal, and the patches are not elevated. In pseudo-xanthoma elasticum of Balzer there is an eruption consisting of mesh-like patches of buff-coloured infiltration, lumpy in some places, in others linear. It must be distinguished also from Schamberg's so-called 'cayenne-pepper' condition, characterized by the presence of brownish-yellowish patches on the legs, made up of small puncta, giving rise to a cayenne-like appearance of the skin, found at times on people suffering from varicose veins.

Treatment.—This is difficult; in some cases an energetic exfoliating treatment by resorcin pastes (resorcin, ʒii.; ac. salic., gr. xx.; Lassar's paste, ℥i.) improves the condition after the inflammation induced by the paste subsides.

Mongolian Spots.

Synonym.—Mongolian maculæ.

Definition.—A congenital condition characterized by the presence of dark bluish spots on the lower sacral region, not disappearing on pressure.

History.—The first complete description has been given by Baelz, who found them almost constantly in Chinese, Koreans, Japanese, and Malays. Later Adachi, Ashmead, Martinotti, Consiglio, and others have further investigated the subject. Castor and Fink have made a very complete study of it in Burma; where it is extremely common.

Geographical.—The condition was at one time considered to be limited to Mongolian races, but further investigations show that it is found in other races, including Europeans. Martinotti, and later Consiglio, have found it in Italy. The condition has recently been observed also in North and South America.

Ætiology.—The condition is of unknown origin; it is probably congenital.

Symptomatology.—'Mongolian spots' appear as blackish-bluish or mulberry-coloured, smooth, non-elevated areas. The colour does not disappear on pressure: it is, as already stated, blackish-blue. Some portions of the same spot may be darker than others The texture of the skin is normal; there is no pain and no pruritus. They are mostly roundish, but they may be oblong or almost square; they may be single, but are often multiple, five or six or more, each spot varying in size from ½ centimetre to 12 centimetres and even more. The patch may be sharply limited or the colour may fade gradually into that of the healthy skin. The commonest situation is on the lower spine, sacral region, and buttocks, but they may be found practically on any other part of the body. The patches appear at birth, and, as a rule, disappear between the third and fourth year.

In Burmese, Castor has found that Mongolian spots are extremely frequent, and are situated in order of frequency on the sacral region and buttocks, waist, arms, legs, shoulders, head, face, neck. Castor identifies with the Mongolian spots also the pigmented patches so often found in natives on the oral mucosa, tongue, and lips.

Diagnosis.—The condition is easily recognized, the roundish or variously shaped bluish patches, generally on the sacral region and buttocks, being characteristic; its being present from birth distinguishes it from patches of pigmentation of other origin. The complete smoothness and normal texture of the skin differentiates the condition easily from pigmented moles. In those rare cases in which confusion with some mycotic condition might arise the microscopical examination will clear the diagnosis, no fungi, of course, being present in Mongolian spots.

Course and Prognosis.—The patches generally fade or disappear completely about the third or fourth year.

Treatment.—The treatment is nil, nor is it generally asked for, the patches most frequently being on covered parts of the body.

Tattooing.

Nomenclature.—The word 'tattoo' is derived from 'tattow,' used by Cook and Banks in their journals in 1789. Tattow was derived from 'tau' or 'tatu,' a word which meant 'marking.' The Maori word is 'amoca' or 'moko,' which, however, refers to the furrowing of the skin—a more formidable operation than tattooing.

Definition.—Tattooing is the formation of more or less indelible marks in the skin by means of rubbing pigments or irritating substances into slight wounds made for the purpose.

General Account.—It appears to us that tattooing was originally preceded by face and body painting, which in the form of 'war paint' is well known to have been used in many savage tribes when about to enter into combat with their enemies. At first this painting was very simple, and consisted in merely smearing the face with some form of pigment, but eventually in certain peoples it became more and more elaborate. Painting, however, is only a temporary method of adornment, and many peoples have adopted in its place the permanent tattooing. The essential reason for tattooing is the ornamentation of the person, but taking its origin in the custom of painting the face before going to war, it is generally more elaborate in men than in women.

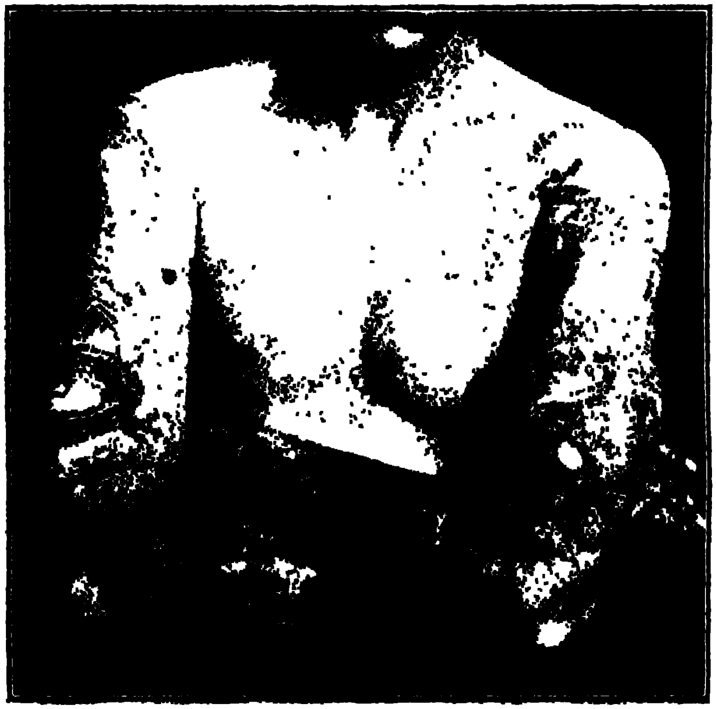

FIG. 877.—TATTOOING.

In Africa the marks have a most varied significance. Thus, according to Hobley, the Ja-Luo girls are tattooed because it is thought that unless this is done a woman will not bear children. Among the Ketosh, the warrior, after killing an enemy in warfare, has two rows of marks tattooed on his right chest and shoulder, to prevent the spirit of his dead enemy bewitching him.

In its simplest form it is seen in West Africa, where short straight skin-cuts are made by means of a sharp piece of iron, after which some pigment or irritating substance is rubbed into the wound, the idea being to produce a keloid. If this fails, another cut is made into the same place, and more pigment is rubbed in until the desired result is attained. These cuts, and hence the subsequent keloids, are arranged in some primitive form of pattern. More elaborate patterns, however, may be met with, being generally in the forms of curved lines or scrolls of keloids. Various types of tribal keloid tattooing have been recently studied by Miss Zaborowska.

In the Naga Hills of Assam the lines of the tattoo follow the contours of the face.

The most elaborate designs are found among the Maoris of New Zealand and the natives of the Pacific Islands. The Polynesians use lines and curves, but not spirals, the highest art being found among the Marquesans. The Maoris are, however, not content with mere tattooing, in which pigment is rubbed into slight cuts, for in their 'moko' they make deep furrows, which remain more or less permanently during life. According to Ling Roth, the Maoris use seven patterns: the first, *the linear*, composed of lines of dots or strokes; the second is *the mat* or *plait-work pattern*, composed of parallel lines, in groups of three, arranged more or less alternately; the third is *the ladder pattern*, in which the lines are arranged in horizontal groups separated by clear spaces; the fourth is *the chevron pattern*, being composed of coils with long tails or handles, the interspaces between which are filled in by slanting lines; the fifth pattern is *the circinate coil;* the sixth, *the anchor;* and the seventh, *the trilateral scroll.* This last pattern is said to imitate a flower—*Clianthus puniceus*. According to the same author, the Papuans are much addicted to the use of the spiral in tattooing. The Polynesians use simple pricking instruments, while the Maoris, in order to produce the deep furrows, use special instruments, shaped somewhat like a miniature garden-hoe, the cutting edge of which is toothed. These instruments were at first made of bone or hard wood, but later iron was introduced. They are made to cut the skin by means of blows from a hammer or a stick. As a result of the wound the blood flows freely, and is wiped away by the hand or a piece of stick, after which the pigment is rubbed into the wound. The nature of this pigment appears to vary, and may consist of charcoal, obtained by burning various animal or vegetal substances. The hair of the beard has to be pulled out by the roots, as it would spoil the effect of the tattoo or moko.

The pain of the operation of moko is naturally very great, especially when performed on the lips, and hence but little tattooing can be done at a time, and it takes years for an extensive moko to be produced. Inflammation often sets in, and it may be weeks before the wounds heal. The Maoris perform post-mortem tattooing and moko at times, but this is to be distinguished from tattooing made during life by the appearance of the cuts and the absence of subcutaneous colour.

In modern times the art of tattooing has been much developed by the Japanese, into whose country it was introduced about 300 years ago. The Japanese artists, by using special instruments, composed of fine and coarse needles, and by rubbing in various coloured pigments, produce the well-known designs so commonly seen on the arms and bodies of Europeans and Asiatics.

Varieties.—The different varieties of tattooing described above may be classified as follows:—

I. Simple tattooing.
  (*a*) Without furrows—tattooing of Japan and elsewhere.
  (*b*) With furrows—moko of New Zealand.
II. Keloid tattooing—tattooing of Africa.

Tattooing is not free from danger, for blood-poisoning, and even death, may result, while syphilis and tuberculosis of the skin may be acquired through the wounds.

Treatment.—When the marks are small, excision may be resorted to, but in general any attempt at removal fails. Nieurowsky removes the tattoo marks by blistering with Finsen light applied in the same way as for lupus. Carbide snow may also be used, but the application must be prolonged, and a scar results. When the tattooing is performed with gunpowder, it is said that the marks can be removed by painting with di-iodide of ammonium in solution, and afterwards with dilute hydrochloric acid.

Ainhum.

Synonyms.—Quigila (Brazil), Sukha Pakla (India), Faddidite (Madagascar), Gundurum, Affovi-burunkue (Gêgês tribes), Bankokerendé (Sudan), Excresis Spontanea (A. Collas), Dactylolysis essentialis (G. Beauregard), Silva Lima's disease (Egas Moniz de Aragao), Esola or Ombanja (Benguelo, West Africa).

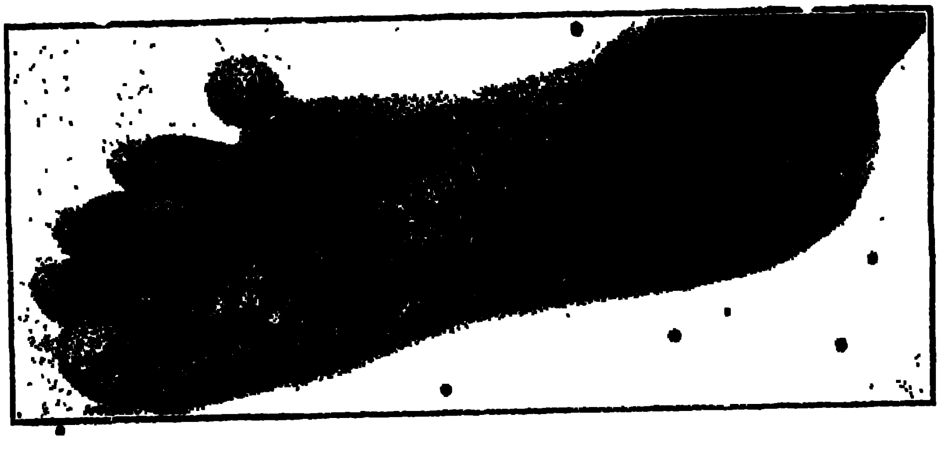

FIG. 878.—AINHUM.

'Anyum,' or 'ainhum,' is derived from a Yoruba word meaning to saw or to cut, and is used by the Nagôs.

Definition.—Ainhum is a chronic disease of the fifth, and more rarely of the fourth and other toes which occurs in native races, and is characterized by the formation of a furrow at the digito-plantar fold, which deepens and extends until it encircles the toe, which is finally severed from the foot.

History.—The disease was first described by Da Silva Lima in 1852. Clarke, in 1860, in his description of the Gold Coast, drew attention to a dry gangrene of the little toe found in negroes in that region, and considered it to be a manifestation of yaws. In 1867 Da Silva Lima further studied the disease, and with Wucherer described fifty cases of it in Brazil, and introduced the term 'ainhum'; in the same year Collas wrote an account of the disease. Da Silva Lima ventured no explanation of the disease. In 1873 Crombie described the disease as occurring in India; in 1876 Pirovano found it in Buenos Ayres; and in 1877 Corre mentions it in Réunion.

It is reported in the West Indies by Potoppidian in 1879; in North Carolina by Hornaday and Pitman in 1882; in Nossi-Bé by Deblenne in 1883; in Western Virginia by Duhring in 1884. This last observer, along with Wile, studied the disease microscopically, considering the essential pathological feature to be an inflammatory œdema of the hypodermis. In 1886 Eyles wrote an excellent account of the pathological histology of the disease as seen in the Gold Coast, concluding that irritation caused an internal proliferation of the epithelium, which, extending into the cutis, damaged the vasomotor nerves, leading to a spasm of the vessels, endarteritis obliterans, fibrosis of the cutis, and rarefying osteitis, whereby the digit is separated from the foot. After this date there are a number of papers, among which may be specially mentioned those by Moriera, Dalgetty, and Maxwell in 1900, Muir in 1903, Ashley-Emile in 1905, and Egas Moniz de Aragão in 1910.

Climatology.—The disease is known in South America, especially in Brazil and the Argentina, and also in British Guiana; in North America, especially in the Southern United States, but also, though rarely, in the Northern, and in Canada. It also occurs in the West Indies. In Africa it is especially well known on the West Coast, and particularly in the Gold Coast, but it also occurs in Algeria, Egypt, Sudan, East Africa, Madagascar, and the Transvaal. In Asia it is known in India, China (?), and Ceylon. It also occurs in Polynesia. We have seen a case in an Italian peasant.

Ætiology.—The causation of the disease is not known. The theories suggesting that the disease is due to leprosy, wearing rings, or other tight bands, self-mutilation, may be dismissed at once, as there is nothing to support them.

According to some authorities—Le Dantec, Da Silva Lima, etc. —the hereditary factor has a certain importance. Da Silva Lima quotes the example of a negro family all the members of which presented the condition.

The racial factor has also been given much prominence, for the condition practically occurs only among natives and mulattoes.

Zambaco Pasha, Eyles, and Moreira, are, in our opinion, correct in their view that the reason why the native races are attacked is because they walk barefoot, and that irritation or injury to the skin of the little toe is more likely to occur in negroes, who often are flat-footed. It is more common in males than in females, in adults than in children, and, though it can apparently be found at any age, is most common between thirty to thirty-five years.

We are inclined to believe that the condition is of parasitic origin, the infection taking place probably through the small superficial lesions or wounds which may be found in people going barefooted.

Pathology.—The constant irritation causes the epithelium to proliferate internally and depress the skin, and cause the fibrous tissue of the cutis to proliferate. There is also an endarteritis, by which the blood-supply is gradually cut off the distal portion of the toe, which therefore becomes œdematous and fatty, while the bone undergoes rarefying osteitis, so that the digit is gradually separated from the foot, a process which takes place through the bone of a phalanx. The histological examination at the line of the furrow shows proliferation of the epidermis, which projects downwards into the cutis, in which the connective tissue is increased in quantity. The vessels show endarteritis and periarteritis; the sweat-glands show proliferation and fatty degeneration of the cells. The bone is in a condition of rarefying osteitis.

Distally to the furrow the joints are effaced; the tissues show fatty degeneration and œdematous infiltration. No organisms can be found.

Symptomatology.—The disease is purely local, and is not, in our experience, attended by any general symptoms. It begins, as a rule, as a furrow on the inner side of the digito-plantar furrow, which slowly deepens and extends laterally and dorsally until the two wings meet on the dorsum of the toe. While this is proceeding the distal portion of the toe becomes swollen, and may appear as a small globule surrounded posteriorly by a deep groove, by which it is separated from the rest of the foot. Often an ulcer forms on the inner side of the groove, and may cause much pain.

Left to itself, the disease will last from two to ten years, though cases have been reported of fifteen to fifty years' duration: but eventually the toe drops off, or is knocked off, or is removed. The process may, however, begin again in the stump.

Usually the fifth toe is affected, but in about 10 per cent. of cases the fourth toe may be affected, and much more rarely the second or the hallux. There are reports of the affection occurring also in the fingers.

Diagnosis.—The diagnosis affords no difficulty, the presence of the constricting furrow being typical. It is easily differentiated from leprotic lesions of the toes by the sensibility being normal and by the absence of signs of leprosy in other parts of the body.

The history makes the diagnosis clear between true ainhum and a peculiar congenital ring-like constriction of the toes described by some authors. This condition is present at birth, and its course is not progressive.

Prognosis.—There is no danger to life in the disease.

Treatment.—The disease is best treated by making a longitudinal cut into the groove, when its progress may be stopped.

Prophylaxis.—The essentials of the prophylaxis are cleanliness, and the wearing of stockings and boots to protect the foot from injury.

Symmetrical Palmar Erythema.

Chalmers, in 1899, drew attention to a symmetrical non-pruriginous palmar erythema found in Europeans on the Gold Coast, and extending along the ulnar side of the palms of the hands. The affection was very persistent. We have seen similar cases in Ceylon.

Acrodermatitis Vesiculosa Tropica.

Historical and Geographical.—This skin disease was described by Castellani in Ceylon. It is of rare occurrence.

Ætiology.—This is unknown, but the affection may be of neuritic origin. It does not seem to be connected with leprosy, in all our cases the search for Hansen's bacillus being negative, and anæsthesia and other signs of leprosy being absent. No history of traumatism was elicited in our patients.

Fig. 879.—Acrodermatitis Vesiculosa Tropica.

Symptomatology.—In a well-marked case the skin of both hands, especially the fingers, appears glossy and tense, the fingers assuming often a tapering shape. Translucid vesicles the size of a millet seed or little more are seen deeply embedded in the skin of the fingers. They have clear contents, and the bacteriological examination reveals absence of any bacterium. They may apparently remain unchanged for a long time, then may slowly disappear; or a few may break, leaving very small superficial ulcers, which heal spontaneously and do not coalesce. The patient generally complains of very severe pains in the hands and fingers, which may be continuous, or may be of a neuralgic intermittent type. Pruritus is absent. There is often diffuse hyperæsthesia; anæsthesia is never present. No thickenings are found along the nerves of the arm. The general health is not affected.

Course and Prognosis.—The course of the disease extends to several months, and occasionally to two or three years, with periods of great improvement. Ultimately the condition may get cured spontaneously. The general health is not affected, but the patient is unable to work with his hands.

Diagnosis.—This is based on the patient complaining of severe pains in the hands and fingers, on the presence of deep-seated cheiropompholyx-like vesicles, on the glossy skin, and on the long course of the complaint.

The condition is differentiated from cheiropompholyx by the severe pains and absence of hyperidrosis; from a leprotic condition by the absence of anæsthetic patches, and absence of other signs of leprosy on other parts of the body. Moreover, though the course is long, the disease generally becomes cured spontaneously. From dermatitis repens of Crocker and acrodermatitis perstans of Hallopeau by there not being history of traumatism, by absence of exfoliative lesions, by the less severe objective signs, and by the absence of the large foci of disease with marked borders and fringed with sodden epidermis, which is thrown up by the undermining exudate.

Treatment.—The regular application of an ichthyol ointment (2 to 5 per cent.) to the hands and fingers, and the administration of the same drug (gr. iii.) three times daily by the mouth is beneficial.

CRAW-CRAW.

Synonym.—Nodular dermatitis (A. Plehn).

Ætiology.—The cause of the malady is unknown. Pijper has described a diphtheroid bacillus.

In the Ceylon gaols, where the disease is common, the prisoners believe it is due to the diet and to the manner of cooking the rice.

O'Neil described in his case a *Microfilaria* which Manson is inclined to believe to be probably *Microfilaria perstans*. Nielly described, under the name of 'dermatose parasitaire' or 'craw-craw,' a papulo-vesicular eruption in which he found nematode embryos in the papulo-vesicles and blood of the general circulation. The conditions described by these authors are not the dermatosis we call craw-craw, and resemble more what Daniels and ourselves call cooly itch.

Symptomatology.—Under the term 'craw-craw' African natives denote practically any pruriginous skin disease. Our African experience has taught us that most of the so-called craw-craw cases are cases of neglected scabies or of tinea corporis, or what Daniels and ourselves call cooly itch. We apply the term 'craw-craw' to a dermatosis met with in Africa, in Ceylon, and in various parts of the tropics, characterized by the presence of numerous hard, *almost horny* papules, occasionally slightly exfoliating at the top, varying in size between a millet-seed and a small pea. Some of the papules may be follicular. They are not of constant shape; some may be roundish and flattened, and others acuminate. When disappearing, they may leave zones of hyperpigmentation. The eruption generally affects the legs and arms, but may spread to the whole body, excepting, as a rule, the face and scalp. Suppurative and ulcerative lesions are absent, except as secondary lesions due to scratching. The proximal lymphatic glands may be hard and enlarged. The disease, if not properly treated, may last many months, and even several years; some cases, however, become cured spontaneously.

Diagnosis.—The disease with which craw-craw presents the greatest resemblance is prurigo. It is distinguished from prurigo by the eruption appearing at any time of life, and not only in childhood; by most of the papules being larger, of horny consistency, and not covered by a small bloody crust, as is often the case in prurigo; and by the fact that it may be cured spontaneously.

The disease may be distinguished from tinea corporis by the absence of any fungus, and from scabies by absence of burrows, and, of course, the absence of the *Acarus*.

Treatment.—The regular application of a salicylic spirit lotion (2 per cent.), followed by β-naphthol ointment (5 to 10 per cent.) for long periods of time, often induces a marked improvement, and in many instances a cure. Internal treatment (arsenic, ichthyol, etc.) does not seem to influence the disease.

FIG. 880.—CRAW-CRAW

Dermatitis Pruriginosa Tropica (Cooly Itch).

The term 'cooly itch' is often applied to dermatoses of various nature, including scabies. We use it to denote an extremely pruriginous dermatitis affecting coolies and occasionally Europeans in certain parts of the tropics, especially in the low country. No acari or similar parasites are found.

Ætiology.—The ætiology is unknown; neither fungi nor animal parasites have been found. It may possibly be due to some parasitic agent which remains on the body only for a short time in analogy to Copra itch (p. 2215).

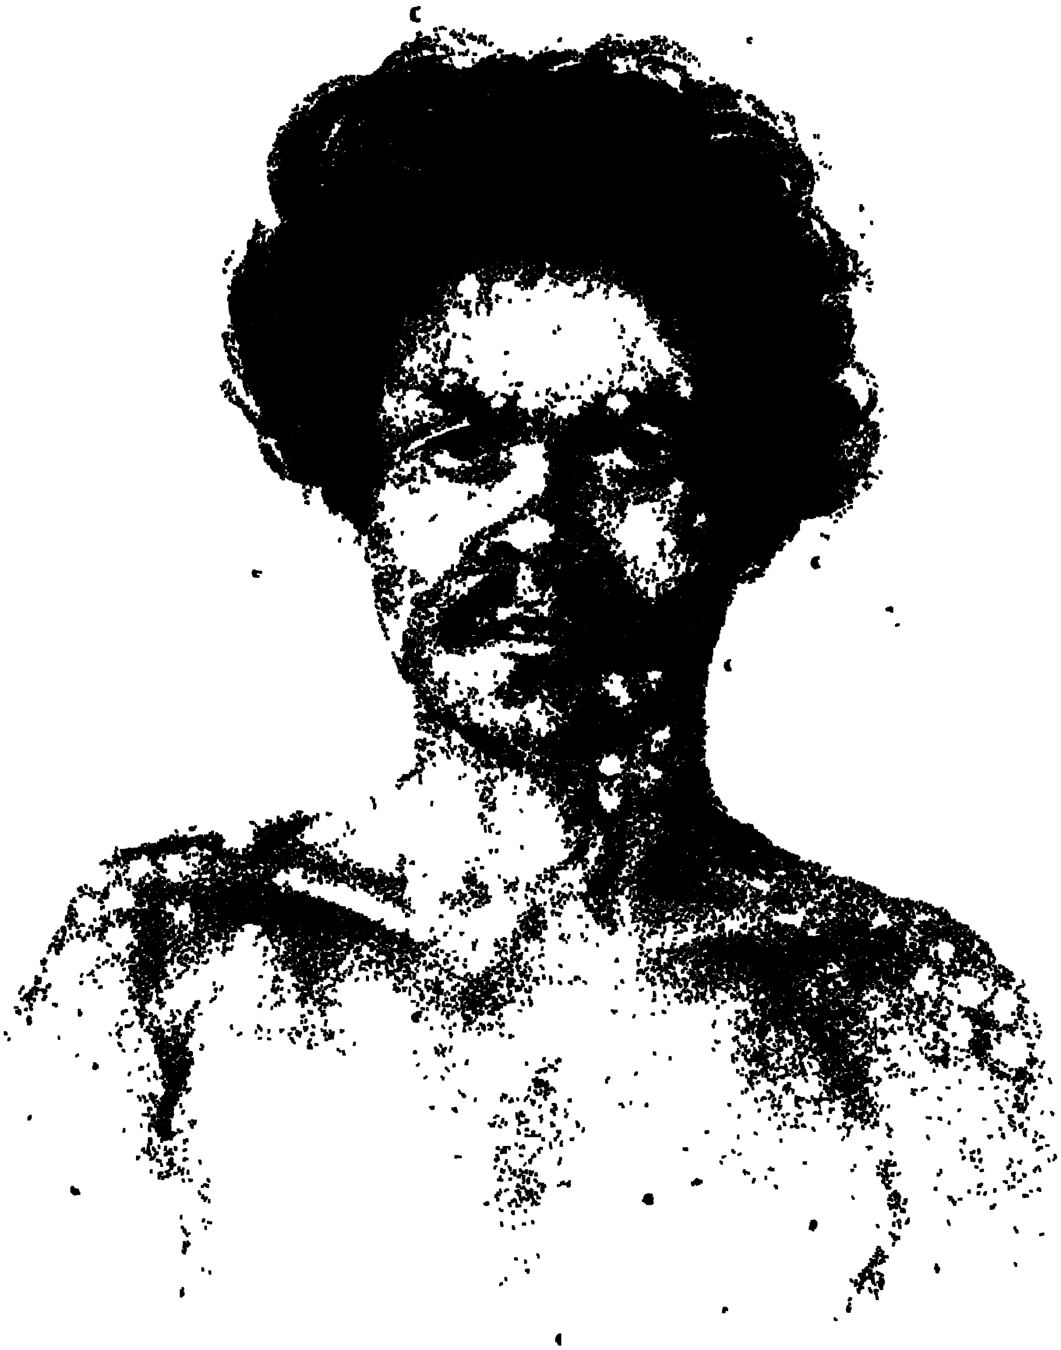
Symptomatology.—The eruption is generally found on the arms and legs, but may extend all over the body, even, though rarely, to the face. The patient complains of unbearable pruritus. The eruption is made up of small papules often covered by bloody crusts; vesicles, papulo-pustules, and pustules may be present, and the patient, on superficial examination, may be considered to be suffering from scabies, but no cunicula are found, and no acarus is observed.

Prognosis.—The eruption is very obstinate, and may last for months.

Diagnosis.—The absence of cunicula and of the sarcoptes differentiates it from scabies.

Treatment.—Sulphur (3 to 10 per cent.) and naphthol ointments (3 to 10 per cent.) are very useful, though their action, as remarked by Daniels, is much slower than in scabies.

PLATE XVI.



DERMATITIS NODOSA RUBRA.

IN REALITY THE PAPULES ARE OF A BRIGHTER ANGRY-RED COLOUR.

[illegible]

To face page [illegible]

DERMATITIS NODOSA RUBRA.

Historical and Geographical.—This condition has been described by Castellani in Ceylon.

Ætiology.—This is unknown.

Symptomatology.—The first impression received on seeing a patient suffering from this peculiar disease is that he is suffering from smallpox in the papular stage of the eruption, but the absence of fever and the closer inspection of the eruption will exclude smallpox at once. In a well-marked case the patient presents on his face, arms, chest, back, and practically on the whole body, numerous large papules and nodules. The colour of the eruptive elements is an angry red; the shape, hemispherical or roundish; the size, from a small split-pea to a large pea. The surface of the papules and nodules is smooth, does not show umbilication, nor scales; their consistency is hard; most of the papules are not follicular. There is unbearable pruritus, but the malady has no urticarial element whatever. Several of the superficial lymphatic glands are enlarged and hard. In several cases a well-marked enlargement of the parotid gland is present. The blood shows a certain degree of eosinophilia. The course of the disease is long—six months to a year, and sometimes much longer; the nodules become gradually smaller, and may disappear completely; they leave no scar or zones of hyperpigmentation, but occasionally the skin may take a slightly scaly or eczematoid appearance. Recurrences may be observed.

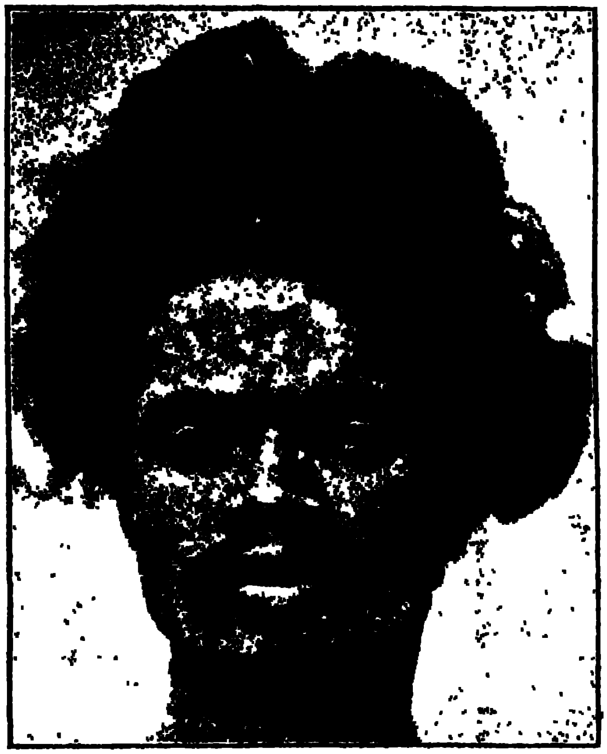


FIG. 881.—DERMATITIS NODOSA RUBRA.

Diagnosis.—From a *syphilide* by the extreme pruritus and the inefficacy of mercury and potassium iodide.

From *smallpox*, the papular stage of which it closely resembles, by the absence of fever, by the chronic course, and by the fact that the papules never undergo a purulent change nor leave scars on healing.

From *lichen planus* by the papules being very large, and by their not being flattened, umbilicated, nor polyhedric.

From *pityriasis rubra pilaris* by the papules being very large, and most of them not follicular, and by the absence of plugs and scaling.

From *acnitis* by the unbearable pruritus and by the eruption not being chiefly limited to the face, as well as by the absence of subsequent necrosis.

From *folliclis* by the condition not being limited to the extremities, and by the absence of central crusts.

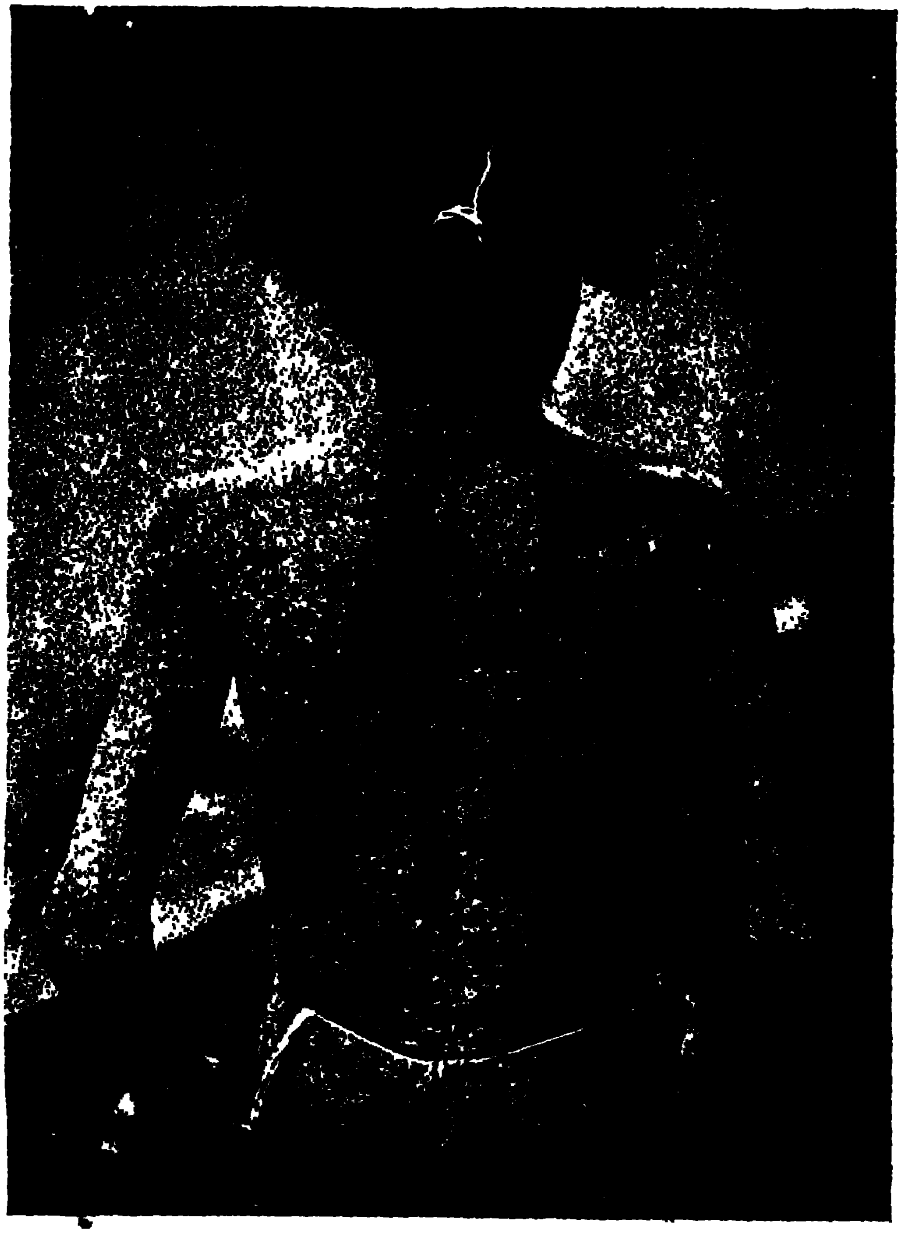

FIG. 882.—DERMATITIS NODOSA RUBRA.

From *erythema multiforme* by the eruptive elements being well-defined, persistent, solid papules and nodules.

Prognosis.—In most cases the general health is not much affected, but the patient complains of the disfigurement and the severe pruritus, and the course of the disease is a long one. Occasionally, after many recurrences, death ensues.

Treatment.—Arsenic, potassium iodide, mercury, do not influence the disease. To allay the pruritus salicylic alcoholic lotions (2 per cent.) and ointments may be used.

LICHEN CONVEX.

Synonym.—Lichen Pilaris Convex (Castellani).

Historical and Geographical.—This affection—which has been described by Castellani—is very common in Ceylon, especially among natives.

Symptomatology.—The regions of the body mostly affected are the thorax, dorsum, and shoulders. The disease is characterized by the presence of numerous firm papules, all of which are follicular. The surface of the papules is smooth; no squamæ or plugs are found; they have always a convex surface, and may be almost hemispheric, $\frac{1}{12}$ to $\frac{1}{8}$ inch in diameter. The colour of the papules has a pinkish hue in natives, and red in Europeans; they have no inflammatory base, they are not surrounded by any halo of inflammation, nor is there hyperpigmentation, nor do they leave pigmented areas on healing. The eruption is very pruriginous. The regions affected may show hyperidrosis. The general health is not affected; the lymphatic glands are not enlarged; in a few cases the blood may show a slight degree of eosinophilia.

FIG. 883.—LICHEN CONVEX.

The course is long, the eruption lasting about three to nine

months, and often recurring. When the eruption heals, no hyperpigmentation is left.

Diagnosis.—From *pityriasis rubra pilaris* by the papules never showing plugs and by the absence of scaling; from *lichen planus* by the papules not being flattened, nor polyhedric, nor umbilicated; from *dermatitis nodosa rubra* by the papules being always follicular and not so large; from a *syphilide* by the intense pruritus; from *papular eczema* by the papules being always follicular and larger and dome-like, with absolutely no inflammatory base, and by the skin not presenting a diffuse inflammation, whatever the stage of the disease. Moreover, even when the eruption is of long standing, the appearance of the skin between the papular elements remains quite normal, and there is no sign of what the French call *lichenification.*

Prognosis.—The eruption lasts for several months, but generally heals spontaneously; recurrences are observed. The general health is not affected.

Treatment.—Potassium iodide, mercury, and arsenic have no effect. Externally, antipruriginous lotions and ointments may be used—as, for instance, a salicylic alcoholic lotion (2 per cent.), followed by a naphthol ointment (2 to 5 per cent.). Change to a cool climate is very beneficial. One of our cases improved on a vegetarian diet.

SYMMETRICAL EAR NODULES.

This condition has been described by one of us in Ceylon in 1910, but further experience will probably show that it is to be found also in other tropical countries. In the deep substance of the lobule of both ears generally the condition is symmetrical—on palpation, a spherical nodule, hardly visible, is felt. Now and then the nodule becomes much larger, very tense, and may then present a somewhat translucid appearance: after some days it becomes smaller again, and may be hardly visible. There is, as a rule, no subjective symptom during the periods of quiescence; a feeling of tension and slight pain during the periods of increase of size of the nodules.

The condition is not leprotic, there being no anæsthesia or other sign of leprosy: it may possibly be of parasitic origin, but nothing definite can be stated, as none of our patients would allow the removal of the nodule. Further investigation may show that it is allied to the peculiar condition called Nepaul tumour (see Chapter XC., p. 2010).

EAR LIPOMATA.

Symmetrical lipomata of the lobules are not rare (see Chapter XC., p. 2010).

PORTER'S LIPOMATA.

Porters and hammock carriers often show one large lipomatous mass on one or both shoulders, where they carry weights, or where the pole on which the weight is carried presses.

SUBCUTANEOUS NODULAR LIPOMATOSIS.

Synonym.—Polymicrolipomatosis.

This condition seems to be common in the tropics in Europeans and natives alike. It is characterized by the presence of subcutaneous nodules, found only on palpation, roundish or oval, painless, the size of a pea to a nut. These are generally situated in the subcutaneous tissue of the arms, legs, and abdomen, and in our experience are not rarely mistaken for enlarged lymphatic glands. On tapping them with a sterile syringe only a trace of fatty material is removed, which, when placed on a slide, promptly dissolves when heated or treated with ether. The microscopical examination of one of these nodules, surgically removed, showed it to be composed of fatty tissue. Occasionally the tumours become much larger and may be plainly visible.

ANGIOFIBROMA CONTAGIOSUM TROPICUM.

This disease was first described by Unna and von Bassowitz. So far, cases have been reported from the southern regions of Brazil only.

Symptomatology.—The incubation period varies from fifteen to twenty-five days. There are no prodromal symptoms. The eruption consists of vivid red papules, which soon enlarge into nodules the size of a large pea to an almond. The eruption may affect any part of the body, but more frequently the face, neck, axillæ, and genital organs. It is rarely found on the legs. It very frequently affects the various mucosæ—oral, nasal, rectal, and urethral. The nodules present a smooth surface, of a violaceous colour, and they are somewhat of soft consistency; they bleed severely after the slightest traumatism. They may disappear spontaneously without leaving any scar, or in other cases secondary infections may set in, and large ulcers develop. The eruption is not pruriginous, there is no fever, and the general health is not impaired.

Ætiology.—This is unknown, but the disease is considered to be infectious. According to Bassowitz, the infection takes place during sexual intercourse, or by the habit the people of Brazil have of taking their maté (national beverage), using the same cannule.

Histopathology.—According to Unna's investigation, the histopathology is quite different from what is observed in framboesia and syphilis. The nodules consist of fibrous tissue, with scanty cells intersected by extremely numerous bloodvessels.

Diagnosis.—The disease must be distinguished from verruga peruviana and framboesia. In verruga peruviana there are severe constitutional symptoms—fever, and often enlargement of the liver and spleen. The condition, however, is considered to be identical with verruga *sensû stricto* (p. 1576), by Strong, Tyzzer, Brues, Sellards and Gastiaburu. In framboesia the nodules have a moriform surface, and do not bleed so easily.

Treatment.—Mercury and potassium iodide are useless. Bassowitz recommends iron and arsenic internally, and externally the injection into the base of the nodules of a few drops of formalin, or their excision, using the galvano-cautery.

MULTIPLE PRURIGINOUS TUMOURS OF THE SKIN.

Schamberg and Hirschler reported in 1905 two cases of multiple tumours of the skin in negroes, associated with itching. The tumours were sharply circumscribed nodules, from the size of a small pea to a large hazel-nut, situated on the extremities. They were of a blackish colour—the smaller smooth, the larger covered with a horny epidermis. These tumours showed, on histological examination, dilated vessels, cellular infiltration, with numerous mast cells, and the formation of new collagenous fibres. The same eruption was previously described in 1880 by Hardway in a white woman.

WEST INDIAN NODULES.

This affection, which seems to be very similar to the preceding one, has been described by Numa Rat in natives of the West Indies, who often confuse it with Guinea-worm. The eruption may attack any part of the body, and consists of subcutaneous nodules varying from the size of a pea to that of a small nut. There is extremely severe pruritus, and the natives destroy the skin covering the nodules with caustics, and extract the nodules, which appear yellowish-white and have a cartilaginous consistency.

Histologically, according to Macleod, they consist mainly of hypertrophied connective tissue made up of thickened collagen bundles. The ætiology is unknown.

MOSSY FOOT.

Synonym.—Piemugoso.

This affection is fairly common, according to Thomas, in the region of the Amazon.

The foot is covered with dense, warty, very vascular, painful masses, as much as a half to three-quarters of an inch thick, which may spread to the leg.

The disease is very chronic, and probably of parasitic origin.

The suggestion has been made by Cranston Low that it may be a type of tuberculosis cutis verrucosa, and by Da Matta that it may be a form of leishmaniasis.

BOTRYOMYCOSIS.

Synonyms.—Botryomycosis Hominis, Granuloma Pyogenicum.

Definition.—A granulomatous condition characterized by the presence of coccal bodies of various size and collected in clusters.

Historical and Geographical Distribution.—The condition was first studied in horses, in which it occurs often in the testicular cord after castration; but it is common also in the pig, dog, and cattle. Later it was found in man by Dor and Poncet in Europe. In the tropics it has been observed in Ceylon by one of us.

Ætiology.—The condition is believed by some observers to be due to an organism (*Botryococcus ascoformans* Kitt, *Micrococcus botryogenes* Rabe), the botanical position of which is not defined. The organism appears in the lesions under the form of spherical bodies of very different size (0·8 to 12 μ), singly or collected in clumps, Gram-positive, and to a certain extent acid-fast. They seem to reproduce by a process of endosporulation. The cultures obtained by some authors have, however, all the characters of a staphylococcus.

Some authorities, in fact, consider the disease to be merely a type of pyosis due to the usual staphylococci. Magrou, using a special technique, has succeeded in experimentally reproducing the disease by inoculating a strain of *Staphylococcus aureus* isolated from an ordinary case of sepsis. M. Nicolle and Cesari have shown that the serum derived from horses affected with botryomycosis neutralizes staphylococcal toxins. Letulle considers the disease to be due to an amœba, and his results have been confirmed by Bureau and Labbé, but not by others.

Pathology.—The condition, as seen by us in the tropics, has all the characters of a granuloma. The microscopical examination of sections shows young connective tissue with large numbers of plasma cells. Peculiar claviform bodies have been described by Magrou, who believes them to originate from the staphylococci. The lesions are very vascular. Later, denser fibrous tissue is observed.

Symptomatology.—The condition generally develops on some suppurating wound, but may occur upon the site of any abrasion or wound. It appears as a small, generally cherry-red, granulomatous nodule or mass, often roundish, of various size—from a pea to a nut or larger. Occasionally the nodule may be pediculated. At first it is of rather soft elastic consistency; later may become fibrous and much harder. There is very little tendency to spontaneous cure. A very mild type of botryomycosis occasionally develops after vaccination. We have seen several such cases.

Prognosis.—The general health is not much affected, but the condition has little or no tendency to spontaneous cure.

Treatment.—Excision, followed by light cauterization with pure carbolic or chloride of zinc, is the only method of treatment. The pedunculated form may be cured by ligature. The disease may occur again after operation, but this is rare.

Prophylaxis.—Care should be taken to keep suppurating wounds thoroughly disinfected.

THE HYPERKERATOSES.

Definition.—A hyperkeratosis is any cutaneous condition in which the cells of the horny layer have a greater coherence than normal, as tested with pepsin and hydrochloric acid, and thus tend to pile themselves up in the form of horny scales.

Remarks.—As defined above, a hyperkeratosis is more a symptom than a disease, and most of the so-called *primary hyperkeratoses* are probably induced by some chemical change produced by an altered metabolic condition brought about by some infection.

Thus syphilis and framboesia tropica are often believed to be the disturbing element which lays the foundation of these changes, even though no sign of their specific germs can be found in the lesions, which may appear long after the disappearance of other features of the disease, while the specific treatment for these complaints has little or no influence on the hyperkeratosis.

Further, syphilis can certainly act upon the fœtus *in utero* and lay the bases of changes of metabolism, which may result in the so-called congenital hyperkeratosis, and the same remarks, to a certain extent, appear to apply also to tuberculosis.

Classification.—With the above provisos, the hyperkeratoses may be classified into:—

A. *Hyperkeratoses obviously associated with a causal disease*:—
  1. *Non-follicular*:
    Found in leprosy, arsenical poisoning, and hyperidrosis.
  2. *Follicular*:
    Found in various tubercular and syphilitic affections, and some forms of lichen and acne.

B. *Hyperkeratoses of unknown origin or remotely associated with syphilis, yaws, tuberculosis, etc.*:—
  (*a*) *Develops during intra-uterine life*:
    Hyperkeratosis universalis congenita.
  (*b*) *Develops during post-uterine life*:
    1. Generalized affections:—
      Of these, *ichthyosis* and *pityriasis rubra pilaris* are met with in the tropics.
    2. Localized affections:—
      (i.) *Non-follicular*:—
        (1) Without acanthosis or markedly dilated papillary vessels—*Keratodermia*.
        (2) Without acanthosis, but with markedly dilated papillary vessels—***Angiokeratodermia***.
        (3) With acanthosis, but without markedly dilated papillary vessels—***Acanthokeratodermia***.
      (ii.) Follicular—*Keratosis*.

In the tropics we have met with leprotic and syphilitic hyperkeratoses, as well as with those connected with lichen planus. We have also seen ichthyosis, pityriasis rubra pilaris, and keratosis palmaris et plantaris, and several other forms; but of all these, three forms must receive a little further notice—viz.:—

1. Keratodermia cribrata.
2. Acanthokeratodermia præcornufaciens.
3. Keratoma plantare sulcatum.

KERATODERMIA CRIBRATA.

Synonym.—Keratodermia punctata.

Definition.—It is a localized non-follicular hyperkeratosis of the hands and feet, appearing in post-uterine life, in which the hyperkeratosic area is riddled with little pits caused by the shedding of little corn-like projections.

Remarks. In the tropics it was first described by Castellani and then by Chalmers.

Ætiology.—It seems that it is in some way associated with yaws or syphilis (congenital or acquired), probably by changes effected in the metabolism, and not by the action of their parasites.

Pathological Histology. The essential points are a mild chronic inflammation of the dermis and a hyperkeratosis of the sweat orifices, leading to the formation of corn-like projections, which are freed laterally and finally all round, and then fall out, leaving a depression.

Symptomatology.—The palms of the hands or soles of the feet may show hyperkeratosis associated with slight itching. In the hyperkeratosic area there are many corn-like bodies, some of which have fallen out and left depressions. The condition is very chronic.

Diagnosis.—The bilaterally symmetrical hyperkeratosis of the palms or soles, with the pits in the thickened areas and the corn-like bodies, are characteristic.

Treatment.—Nothing is known to permanently benefit the condition.

ACANTHOKERATODERMIA PRÆCORNUFACIENS.

This is an acanthokeratodermia characterized by the formation of thickened patches of epidermis in the palms of the hands and soles of the feet, which may (in the latter situation) become cracked and fissured and break down, forming painful sores, which prevent the patient from walking. Sometimes they are associated with a thickening of the horny layer of the nail-bed, thus giving rise to a peculiar elevation of the nail called by Unna *hyperkeratosis subungualis*. Most patients have been affected with syphilis, but the specific organisms cannot be found in the lesions, and antisyphilitic treatment is generally useless. Pathologically the condition resembles that in the first stage of the production of a cutaneous horn, which, indeed, had formed in one case reported by Colcott Fox.

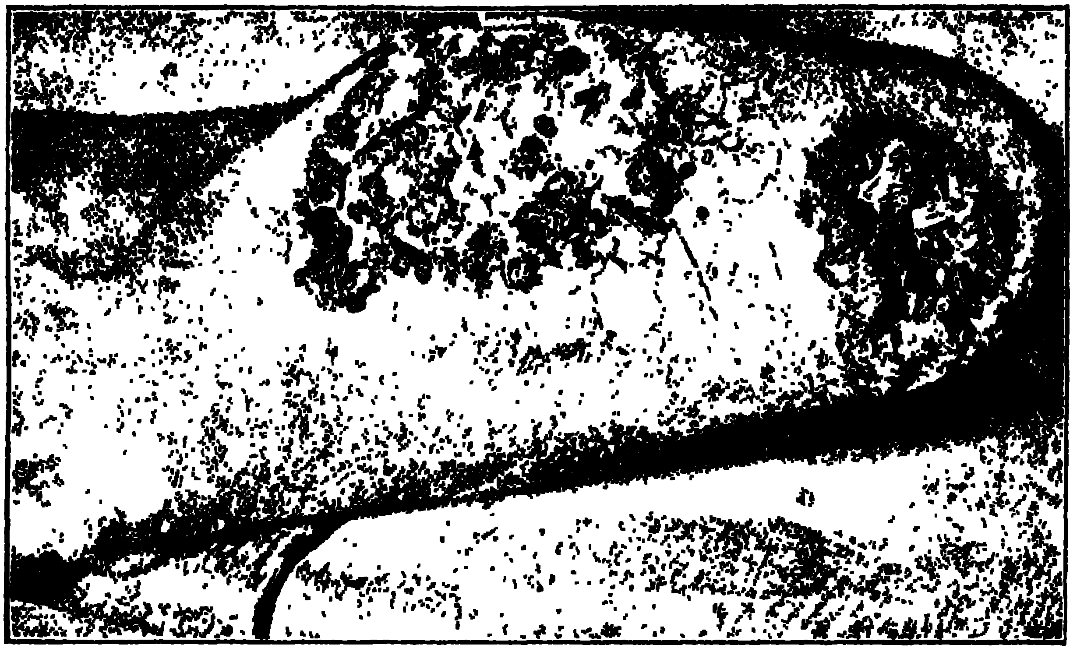

FIG. 884.—ACANTHOKERATODERMIA PRÆCORNUFACIENS.

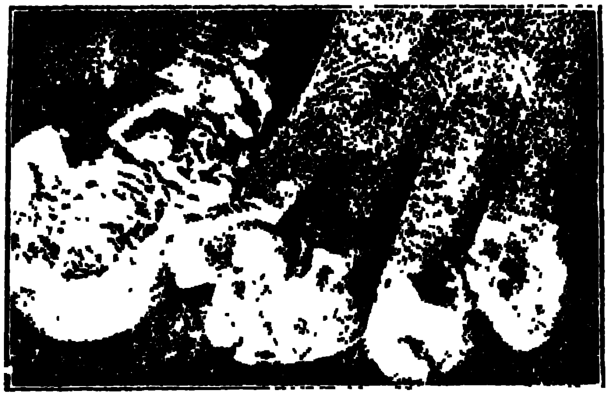

FIG. 885.—ACANTHOKERATODERMIA PRÆCORNUFACIENS.

KERATOMA PLANTARE SULCATUM.

Historical and Geographical.—This disease was first described by Castellani in Ceylon. It is found also in India and tropical Africa, and a case has been recorded in Macedonia.

Ætiology.—This is unknown, though in certain cases yaws may perhaps play a rôle in its causation. The affection is much more frequent during the rainy season, and occurs generally in natives who do not wear shoes or sandals; but we have seen a typical case in a European of good social standing. It improves or disappears completely during the dry season.

Symptomatology.—The epidermis of the soles—especially the anterior portion—and the heels is greatly thickened, and is generally of a dark yellowish colour, and presents numerous deep segmentary furrows, straight, semicircular, or ellipsoid; these furrows appear black, but if the dirt and dust accumulated in them is removed, the fundus of these sulci will be found to be whitish or pinkish. There is no sign of any local inflammation, though the patient generally complains of tenderness of the feet after much walking.

Diagnosis.—This is based on the presence of the characteristic deep sulci and punched-out holes in the thickened epidermis, which are absent in lesions of the soles of the feet of syphilitic origin.

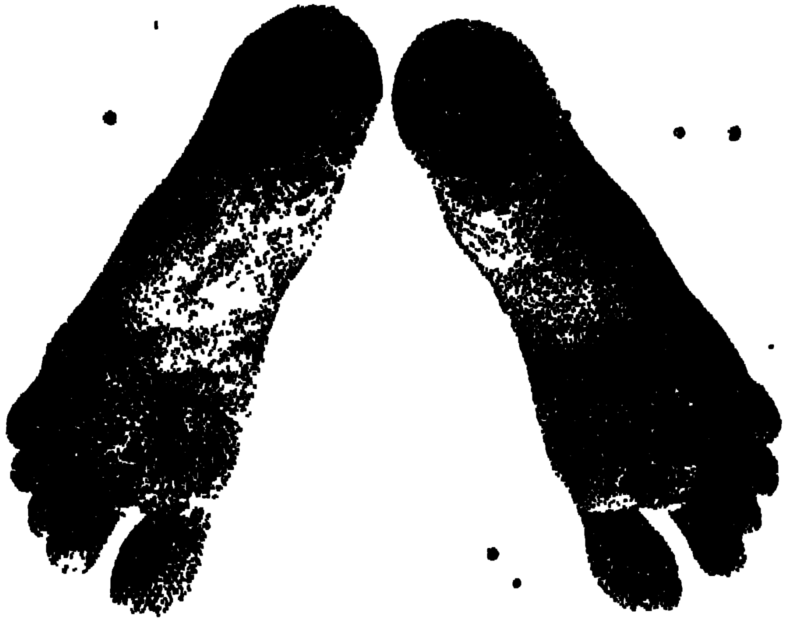

Fig. 886 Keratoma Plantare

Moreover, a mercury and potassium iodide treatment has no effect whatever on the malady. In yaws the lesions of the soles of the feet are, generally, either granulomatous, with large frambœsiform nodules piercing through the thick epidermis, or a diffuse scaly condition with thickened epidermis is observed. The rare pitted condition of the soles of the feet (p. 1550) found in yaws is distinguished by its lack of seasonal incidence and by the history. In the condition known as 'symmetrical keratodermia of the extremities' no deep sulci are found. The so-called 'mal de meleda,' which is very common in the Island of Meleda in the Adriatic, is, according to Neumann and others, identical with symmetrical keratodermia, and no deep sulci are present.

Prognosis.—The general health is not affected, but the condition may last for months, and if the patient has much walking to do, may become very painful.

Treatment.—Potassium iodide, mercury, and salvarsan are useless. Rest and local applications of salicylic ointment or salicylic collodion (ac. salicyl., ʒi.; collodion, ℥i.), or salicylic plasters induce a marked improvement.

JUXTA-ARTICULAR NODULES.

Synonyms.—'Enno,' Naridé, Macgregor's nodules, Steiner's tumours, Jeanselme's nodules.

Historical and Geographical.—This affection was first briefly described by Macgregor in 1901 in New Guinea, who also suggested a possible parasitic origin of it. It was later more fully studied by Steiner in natives of Java and by Jeanselme in natives of Siam, where it is known as 'enno.' Jeanselme introduced the very appropriate term of 'juxta articular nodules.' Fontoynont and Carougeau in Madagascar considered the cause of the affection to be a fungus, *Nocardia carougeaui* Brumpt, 1910. Cases have been observed in Northern Africa by Gros and in Ceylon by us, also by Chalmers and Archibald in the Sudan. The disease will probably be found to occur in many other tropical and subtropical countries.

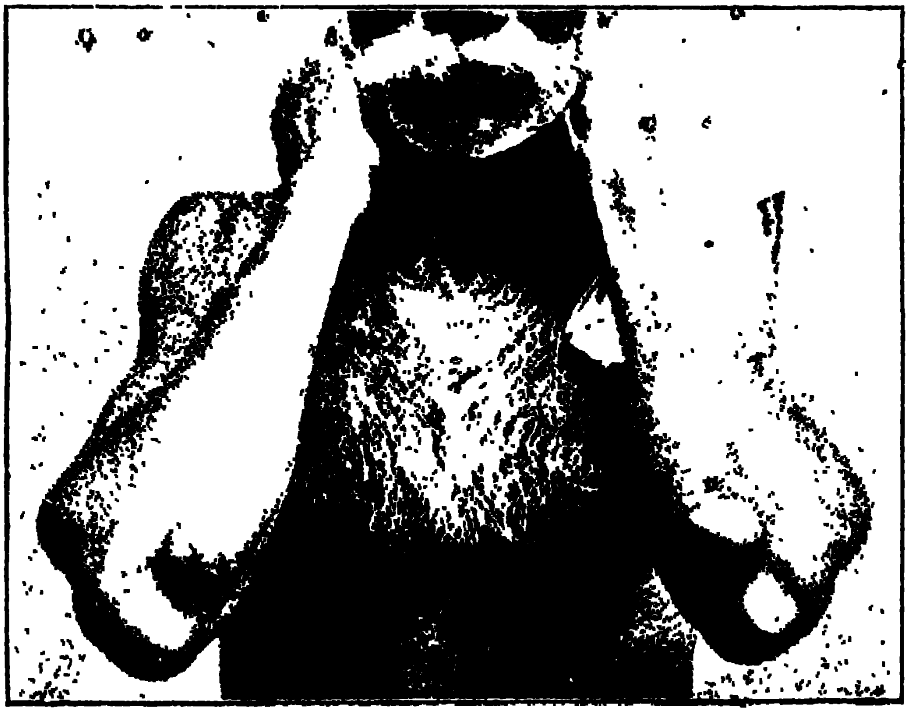

Fig. Juxta-Articular, N

Ætiology.—Macgregor, Steiner, and Jeanselme considered the nodules to be of parasitic origin, while Fontoynont and Carougeau found a fungus which they believed to be the ætiological agent of the condition. The description of this fungus—*Nocardia carougeaui*

Brumpt, 1910—is given in the chapters on fungi (see pp. 1065 and 1066). Recently the presence in the nodules and etiological rôle of this fungus has been doubted by many authorities. Several observers consider the condition [illegible] late manifestation of frambœsia.

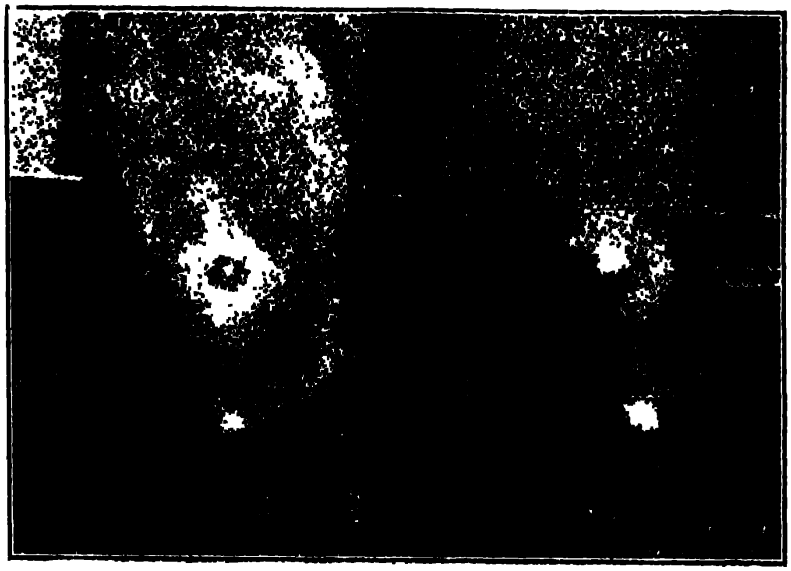

FIG. 888. JUXTA-ARTICULAR NODULES.

Symptomatology. In the legs and arms, especially in proximity to the articulations, several nodules are found, some of them the size of a walnut or more, of rather hard consistency, and covered by healthy skin. According to Macgregor, these tumours occur most frequently about the elbows or the parts of the body coming in contact with the ground when the native is sleeping. These nodules at first are rather soft, and are situated in the subcutaneous tissue, and the skin may be moved above them. Later they may, apparently, fuse together, forming hard, large tumours, and adhere to the skin, which generally does not present any alteration. The course is very chronic, but occasionally the nodules may disappear spontaneously.

FIG. 889. MURMEKIASMOSIS AMPHILAPHES.

Treatment.—The nodules may be excised. In the very first stage of the disease a potassium iodide treatment might be tried.

MURMEKIASMOSIS AMPHILAPHES.

Chalmers and Christopherson have described a case (Fig. 889) of spreading warts, associated with *Cryptococcus myrmeciæ,* which grew on the skin of the face and neck, destroyed an eye, and entered the mouth.

LYMPHO-FIBROMATOSIS.

This is a condition of elephantoid fibrosis (Fig. 890) met by us in Ceylon and Africa. It is sometimes associated with a secondary pyogenic eruption. Some cases may be associated with filariasis, but others are not. The skin is elevated into large, raised, flattened patches of fibrous consistency. The condition is chronic.

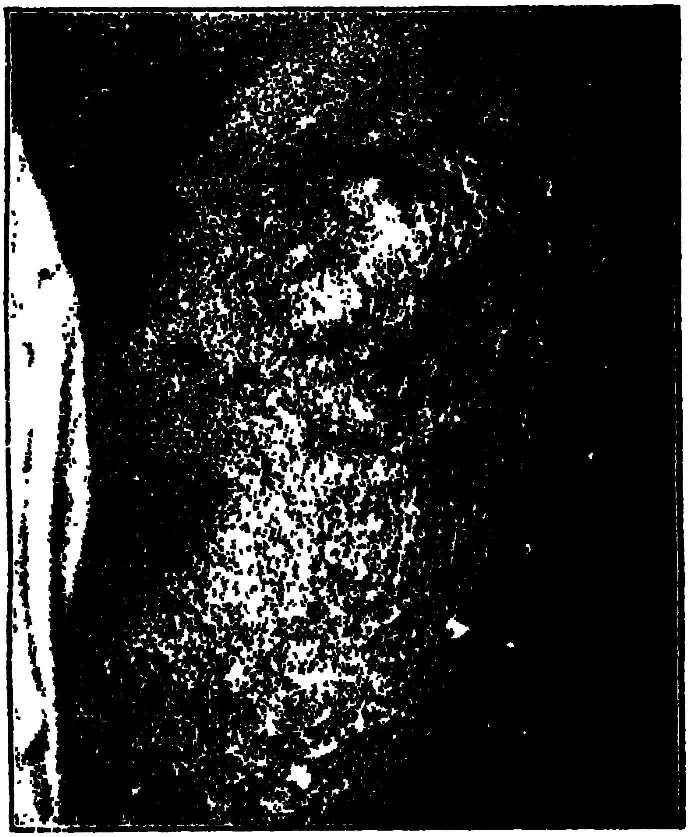

Fig. 890.—Lympho-Fibromatosis.

SEBORRHŒA SPINULOSA.

This condition has been seen by Castellani and Chalmers in various parts of the tropics and the Balkans. It is characterized by the presence of numerous yellow plugs, some of which are acuminate and hard. These plugs project from the orifices of the sebaceous ducts, and are often situate on an oily skin. Ordinary black comedones are absent. The term 'seborrhœa spinulosa' probably covers several varieties of seborrhœa.

CHAPTER XCIX

COSMOPOLITAN SKIN DISEASES

General remarks—Pyogenic infections—The erythemata—The exanthemata—Urticaria—Dermatitis venenata—Parasitic diseases—Bullous eruptions—Herpes—Eczema, psoriasis, seborrhœa, and dermatitis exfoliativa—Acne—Hyperidrosis and bromidrosis—Lichen—Tumours—Tuberculosis—Syphilis—Ichthyosis—Kaposi's disease—Chloasma—Diseases of the hair and nails—Some cosmopolitan diseases of mucous membranes.

GENERAL REMARKS.

IN our experience, all the skin diseases met with in temperate zones are also found in the tropics, except those due to intense cold, such as erythema pernio and frost-bite, and even these may also be found in the high mountainous regions of the tropics.

The diagnosis of some of the cosmopolitan dermatoses may, owing to the colour of the skin of native races, be very difficult to the medical man newly arrived in the tropics. This is probably the cause of some of the statements that such common diseases as lichen planus and psoriasis are absent. There is no doubt, however, that some dermatoses which are frequently met with in temperate zones are less common in the tropics.

It is stated by some authorities that coloured races are, on the whole, less liable to skin diseases than the white races, but the reverse is more in accordance with our experience.

A few remarks as to the normal skin of native races may be useful before proceeding to review the various cosmopolitan diseases. In the African races and American negroes who descend from African negro stock (Guinea negroes, Yoloffs, Caffres) the whole skin, especially the derma, is thicker than in the white races. In Indian races the skin is about the same thickness as in Europeans, except in the Tamils, whose skin is somewhat thicker. As noted by Howard Fox, the glandular system—sweat glands and sebaceous glands—is much more highly developed in the native races, especially the African negroes. The sebaceous secretion is the cause of their peculiar odour and the shining appearance of the skin, and the large secretion of sweat, which, owing to the high temperature, quickly evaporates, is the probable cause of the skin feeling cooler when touched. In native races the hairy system is less developed, except on the scalp; in the African races the hair of the head is generally curly or woolly; in Indian races it is usually smooth.

The slight development of lanugo hair is the cause, as noted by Fox, of the peculiar velvety feeling of the negro skin.

The most important characteristic of the skin of tropical native races is the dark pigmentation. It is said that this pigmentation is not present at birth, but develops within a few hours to several days after birth. In our experience, it cannot be doubted that at the time of birth in many cases the babies present a much lighter colour than the adult people. The skin, however, is not whitish, but of a muddy brownish colour, and darkens greatly within a few days—in some cases is quite dark also at the time of birth. It is said that the pigmentation increases till puberty, and then, after remaining stationary during adult life, slowly decreases during old age. The maximum pigmentation is found on the loins, posterior portion of the trunk, shoulders, buttocks, and thighs; the least pigmentation is found on the prepuce, vulva, palms, and soles. In some races the oral mucosa is not pigmented; in others there is a patchy dark pigmentation which extends often to the tongue. The dark patches on the tongue have been considered by several writers to be a pathological condition, and a sign of ankylostomiasis. We have observed such patches, however, in numbers of normal natives. The hair is said to become white at a later date among negro races than in Europeans; we have not noted any distinct difference, either among them or the natives of Asia.

It is said by some writers that native races, and especially the negro African races, are less susceptible to pain than the white man. In our experience there is hardly any difference in the ordinary dolorific sensibility, but the thermic sensibility is probably less.

PYOGENIC INFECTIONS.

These are very common in tropical countries. **Impetigo** and **Ecthyma** lesions are frequently met with. The symptoms and course are identical with what one finds in temperate zones, and the treatment is the same—removal of the crusts, disinfection with a lotion, such as a perchloride of mercury (1 in 2,000), and dressing with a white precipitate ointment (1 per cent.).

Boils.—This is a common affection in the tropics, very stubborn, and difficult to cure. The quickest and most reliable method of cure in cases of multiple boils is, in our experience, Wright's vaccine treatment, the vaccine being prepared from staphylococci isolated from the patient. When this treatment cannot be carried out, the administration of yeast preparations internally will be found to be useful in some cases—*e.g.*, ceridin pills. Occasionally a small boil may be aborted by applying a droplet of pure carbolic acid by means of a pointed pencil of wood drilled into the centre of the papule. For old indurated boils the continuous application of a carbolic lotion (2 to 5 per cent.) on lint occasionally causes them to become absorbed.

As a preventive, a salicylic alcoholic lotion (1 to 2 per cent.) used after the daily bath is advantageous.

Sycosis coccogenica.—This is fairly common in both Europeans and natives. In the negroes Fox has often observed the formation of tiny cheloidal tumours after this affection. Depilation and the use of a vaccine is the best method of treatment. We have observed a case of *Dermatitis papillaris capillitii* (Kaposi).

Erysipelas.—Ordinary erysipelas due to streptococci, and to be distinguished from the filarial erysipelatoid attacks preceding the development of elephantiasis, is not rare. Ichthyol ointment or lotion (10 per cent.) answers well.

THE ERYTHEMATA.

Erythema solare is common in Europeans recently arrived, and in those who live an open-air life, such as planters. It is followed by pigmentation (sunburn, see pp. 82 and 2231). The application of calamine lotion, followed by the use of boric vaseline or rose-ointment, is beneficial.

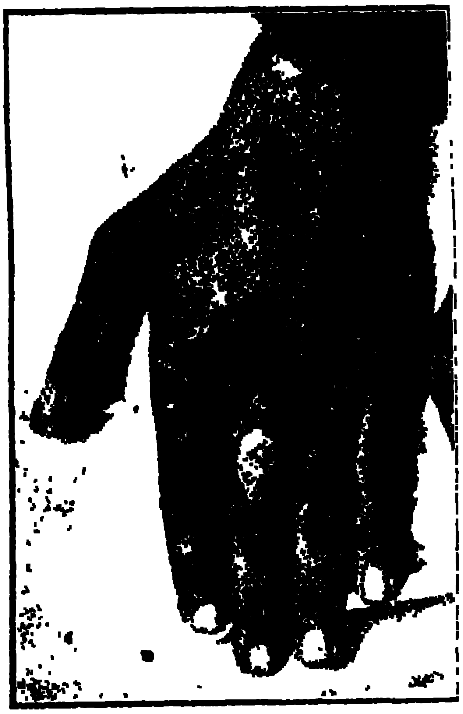

Fig. 89K—Herpes Iris.

Erythema intertrigo is very frequently observed in corpulent persons. Washing the parts with a potassium permanganate solution (1 in 5,000), followed by application of boric-talc or salicylic-talc powder (acid. boric. ʒi., talci ℥i., or ac. salicyl. gr. x., talci ℥i.), is useful. Persons suffering from intertrigo are very liable to become infected with tinea cruris.

Erythema nodosum — Erythema multiforme.—These affections are occasionally met with, but much more rarely than in temperate zones. We have seen two cases of the variety of erythema multiforme known as *herpes iris*.

Erythema annulatum and **Erythema gyratum,** in persons suffering from fever, and coming from tropical Africa, should always arouse the suspicion of trypanosomiasis.

Diffuse **Erythema scarlatiniforme** and **Erythema morbilliforme** may be seen in some malarial patients. They may occasionally be caused by quinine, but in most cases are of malarial origin. The diagnosis of erythemata in dark natives is difficult. The medical man of long experience, however, will be able to detect a peculiar shiny aspect of the skin, with a distinct pinkish tinge.

Purpura.—Schönlein's purpura, Henoch's purpura, and Werlhof's purpura are not common in the tropics, though we have seen cases. A symptomatic purpura eruption is occasionally seen in the last stage of kala-azar, in malaria and other maladies.

THE EXANTHEMATA.

Smallpox, chicken-pox, and measles are very common in the tropics, though scarlet fever is but rarely met with.

Smallpox, of which we have already given a description (p. 1486), is very common, and often spreads in extensive epidemics, and may present the confluent type and the hæmorrhagic type, which is rare in Europe. In colonies under European rule vaccination is extensively practised. The vaccine does not retain its immunizing properties for more than a few weeks in the tropics, and hence it is advisable for each colony to be provided with a central vaccine depot where the lymph can be prepared under careful supervision. Owing to the habits of the lower classes and to many of the vaccinators being non-medical men, serious infections with other diseases may occur.

Measles may be difficult to recognize, as the eruption in dark-skinned races is better felt than seen, but the coryza and other symptoms are generally sufficient to enable a correct diagnosis to be made.

URTICARIA—LICHEN URTICATUS—PRURIGO.

Urticarial eruptions are as frequent in the tropics as in temperate zones, though to the new-comer the diagnosis of urticaria in dark-skinned natives is far from easy. Of **lichen urticatus** we have seen several cases among European and half-caste children, and of **urticaria pigmentosa** we have seen one case—a European child. We have observed true **prurigo** of Hebra in two native girls.

DERMATITIS VENENATA.

Several tropical plants and grasses produce substances highly irritating to the skin, but the subject has already been treated in Chapter XCIV., p. 2151. The dermatitis so caused may be urticarial, erythematous, eczematous-like, or bullous, and may extend to large portions of the body. The forms of dermatitis venenata due to animal agents, such as ants, bugs, caterpillars, etc., have been already mentioned in Chapters XIV. and XCVI., p. 2200.

PARASITIC DISEASES.

Trichophytoses.—In tropical countries, in addition to the trichophytoses peculiar to the tropical climate, several other forms of trichophytic affections occur which are clinically identical with those met with in temperate zones, such as tinea circinata, tinea capitis, tinea barbæ. The fungi are, however, in most cases different species (see p. 2052). In our experience, tinea capitis is less common in India, Ceylon, and tropical Africa, than in Europe and America. On the other hand, it is extremely common in the American negroes. The fungi found in the tropics are generally large-spored ones. *Microsporum audouini* has never been found by us. *Favus* is rare in tropical Africa and Asia, but common in China, Egypt and in the Sudan.

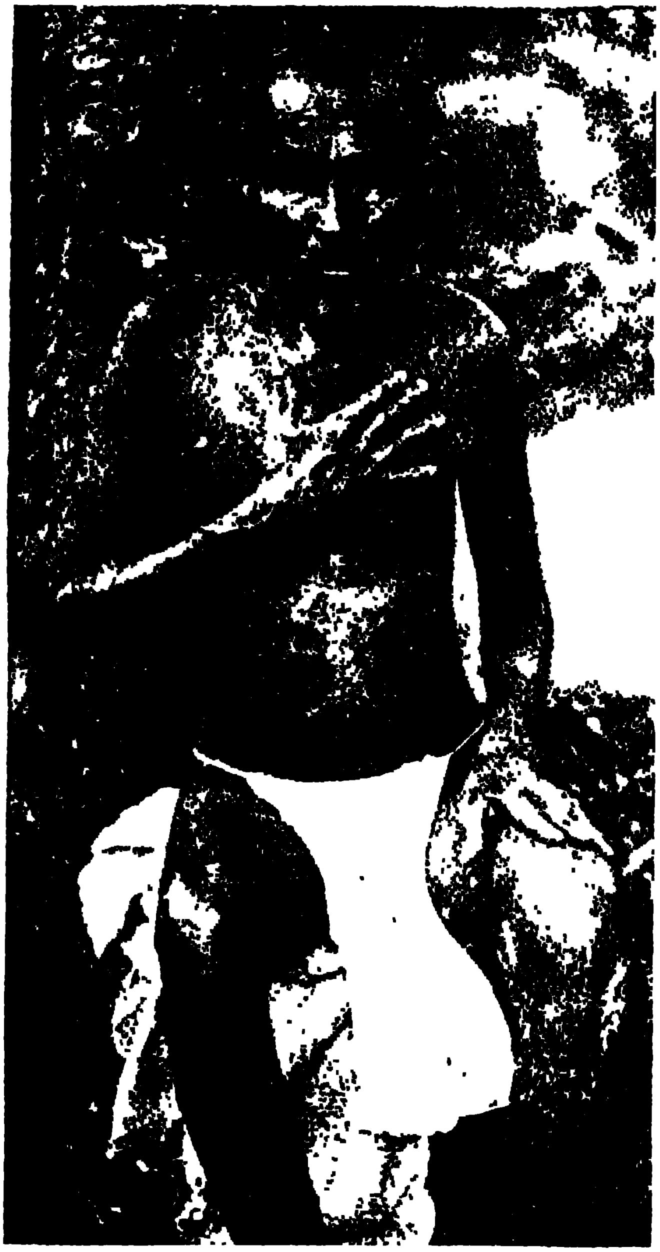

FIG. 892—SEPTIC PEMPHIGUS.

Pityriasis versicolor.—The pityriasis versicolor of temperate zones may be found in the tropics. It is to be noted, however, that several writers on tropical medicine confuse pityriasis versicolor with another dermatomycosis which is extremely common—tinea flava (see p. 2073).

Pediculosis and Scabies. *Pediculosis capitis* is extremely common, although natives generally take great care to keep their hair in good condition by regularly combing, washing, and oiling it. According to Fox, Carmichael, and Pendergast, pediculosis capitis in the Southern States of North America is much less frequent in the negroes than in the whites, as, according to them, the negroes take greater pains in the care of the scalp than do the lower-class whites. *Pediculosis corporis* and *Pediculosis pubis* are as frequent in the tropics as in temperate zones, and so is scabies. *Pediculosis pubis* may, however, be very rare or absent in races accustomed to regular shaving of the pubic hair. For description of the parasites see p. 753. Scabies is described on p. 2217.

BULLOUS ERUPTIONS.

Epidermolysis bullosa is occasionally observed.

Pemphigus vulgaris and **Septic pemphigus** cases are not rare in the tropics. In the cases of septic pemphigus we have always found virulent streptococci. The eruption is similar to what one sees in temperate zones. We have seen a case of **Pemphigus vegetans,** and we have observed a typical case of **Pemphigus foliaceus,** contracted in Ceylon, and another in Indo-China. **Dermatitis herpetiformis** is not rare.

(Of **Hydroa vacciniformis** we have seen two cases in European children.)

HERPES.

Herpes facialis febrilis is common during attacks of malarial fever and other fevers, but very rare, as is well known, in enteric.

We have seen in European children a similar condition to what some French writers call *fièvre herpétique*. The condition, as seen by us, is characterized by a sharp attack of fever lasting about twenty-four hours, and at the same time by the appearance of a few herpetic vesicles—in our cases on the thighs and buttocks.

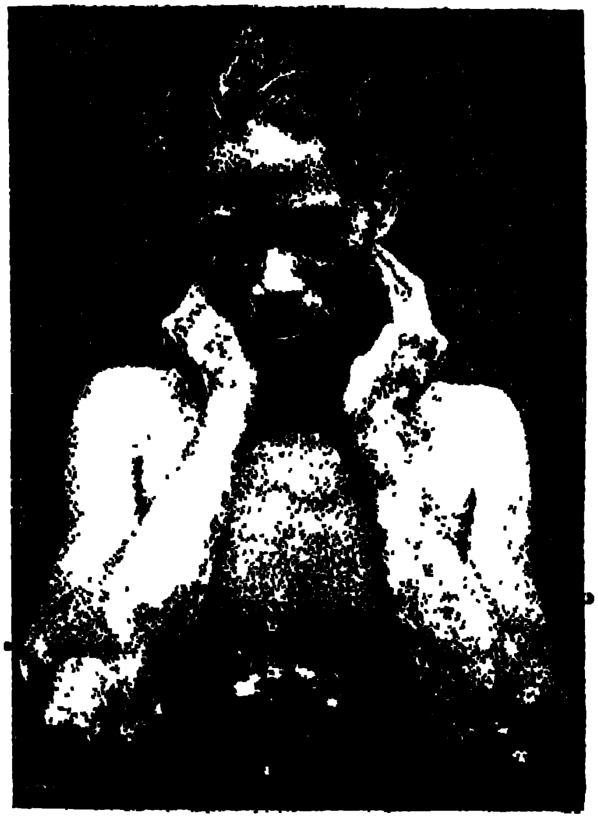

FIG. 893.—PSORIASIS.

Herpes progenitalis is very common, especially in Europeans.

Herpes zoster (zona, shingles) is frequently met with in Europeans and natives.

ECZEMA—ACRODERMATITIS PERSTANS—PSORIASIS—PARAPSORIASIS—SEBORRHŒA—DERMATITIS EXFOLIATIVA.

Eczema is extremely common, and all varieties of it are found in the tropics, as in temperate zones, both in natives and Europeans. The treatment is often very difficult. In our experience greasy preparations and even pastes are as a rule badly borne except in some chronic cases. Generally speaking, it is best to use lotions such as resorcin (½ to 1 per cent.) or liq. plumbi (2 per cent.). Some cases of eczema will improve only on the patient going to a cooler climate. Wilson's **Eczema verrucosum**, characterized by great dryness and hardness and warty appearance of the affected part, is frequently met with among natives, in whom it mostly attacks the toes.

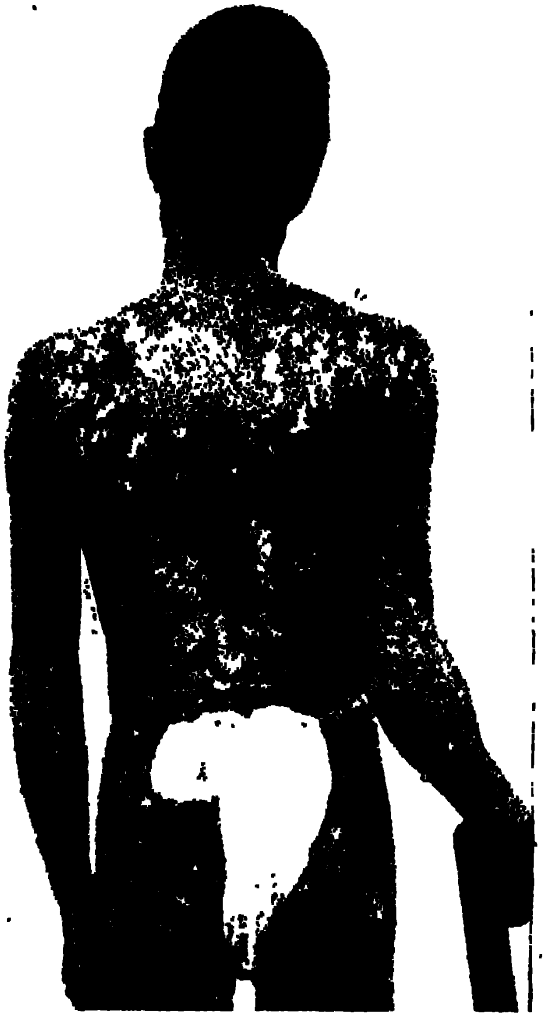

FIG. 894.—PSORIASIS IN A SINHALESE.

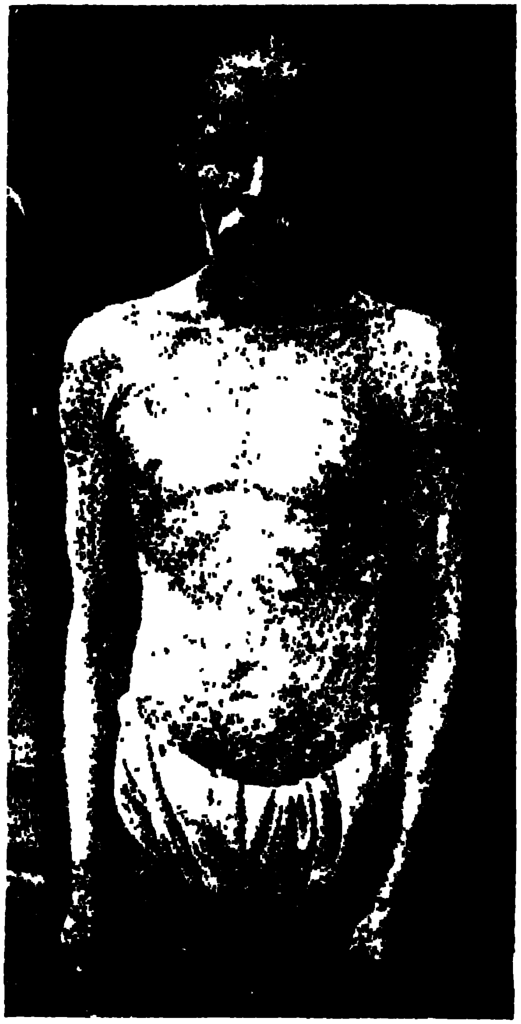

FIG. 895.—DERMATITIS EXFOLIATIVA IN A SINHALESE.

Acrodermatitis Perstans.—We have seen two cases of a very obstinate chronic dermatitis, with exfoliation, on the extremities of Sinhalese natives, apparently identical with acrodermatitis perstans of Hallopeau. They were different clinically from the acrodermatitis vesiculosa described by one of us.

Psoriasis is considered by most writers to be extremely rare or absent in native races in the tropics. Rutz states that he never saw a single case of psoriasis in a negro during his many years of practice in Martinique. Howard Fox, senior, thinks that possibly the savages of Africa are free from psoriasis on account of exposure of the skin to sunlight, and that the negroes of North America have inherited this peculiarity. In our experience, psoriasis is frequently met with in the tropics in Europeans and natives of every race.

Seborrhœic affections are common in the tropics, especially in Europeans. A *seborrhœide* of the chest is frequently met with, and often confused with ringworm. The microscopical examination will clear the diagnosis. The use of a sulphur ointment (5 per cent.) is the best treatment.

In Ceylon a peculiar form of seborrhœa capitis with yellowish scales is occasionally seen in European children between four and twelve years of age. This affection is probably due to *Pityrosporum cantliei* Castellani, 1908, and quickly disappears when the child goes to cooler climates.

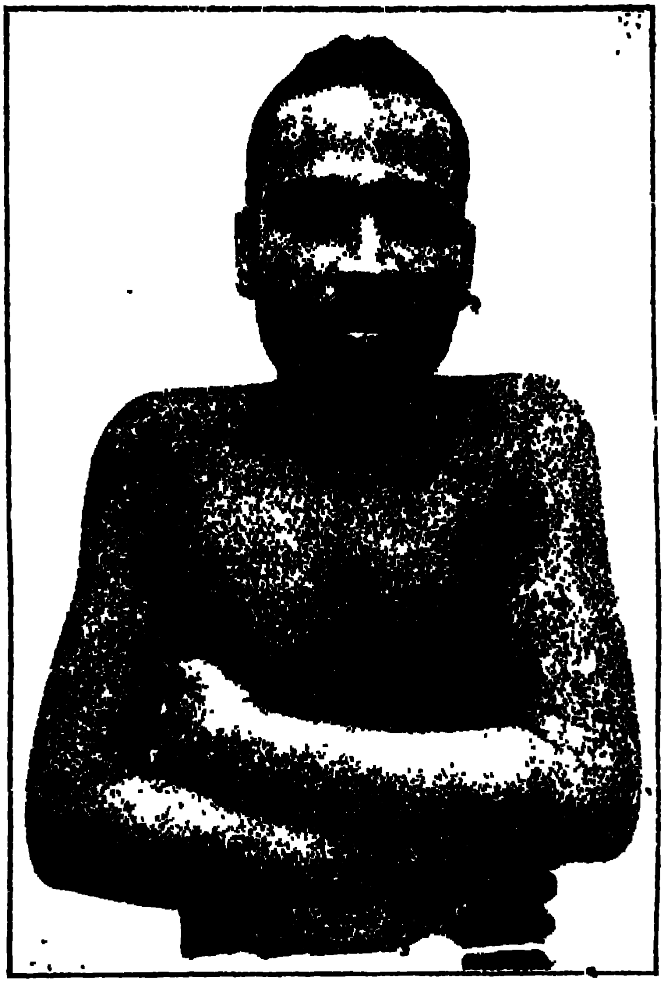

FIG. 896.—DERMATITIS EXFOLIATIVA SIMULATING TINEA IMBRICATA.

Dermatitis exfoliativa (pityriasis rubra) is not rarely met with, occasionally following on psoriasis. In Ceylon we have observed two cases in Sinhalese natives. The amount of desquamation was enormous. On removing the scales, which were white, the skin appeared of an angry red colour. At times, on superficial examination, certain cases may be mistaken for diffuse tinea imbricata.

ACNE VULGARIS—ACNE ROSACEA—ACNE VARIOLIFORMIS—ACNE CHELOID.

Acne vulgaris and **Comedos** are extremely common in all races. Both types of acne—**Acne indurata** and **Acne papulosa et pustulosa**—are observed. The treatment, which is as difficult in the tropics as in temperate zones, is based on the use of medicated soaps and sulphur or ichthyol lotions or ointments. The vaccine treatment may occasionally give good results.

Acne rosacea is, in our experience, comparatively rare in the tropics, though we have seen cases in all races. True *rhinophyma* we have also observed.

Acne Varioliformis.—This, in our experience, is as frequent in the tropics as in temperate zones, and may be found in all races. The regions of the body more commonly affected are the forehead, temples, the front of the sternum, and the interscapular region.

Acne cheloid is very common, especially among native races. The back of the neck is generally affected. Cases of *Acnitis* and *Folliclis* are occasionally seen. These are probably tuberculides.

HYPERIDROSIS AND BROMIDROSIS.

These conditions are, for climatic reasons, very common in the tropics, and have already been considered (see p. 2222). The treatment may be very difficult. Naphthol or salicylic alcoholic lotions (1 per cent.), followed by a salicylic, boric, or tannoform powder, are useful. If there is much inflammation of the skin, no alcoholic lotions should be used, but simply water solutions of boric acid (2 per cent.) carbolic acid (½ per cent.), permanganate of potassium (1 in 5,000), and occasionally hydrargyrum perchloride (1 in 2,000 or 4,000), after which a salicylic or boric powder is applied. The same powder should be sprinkled on the socks and shoes and undergarments. Internal treatment by sulphur, acid drinks, etc., is not of much use. Belladonna and atropin will stop the secretion for a time, but they must be pushed till unpleasant symptoms occur. We have seen a case of *chromidrosis* of the axilla in a native boy due to the presence of a bacillus closely allied to the *Bacillus prodigiosus*, and another due to a red-pigment-producing coccus.

Granulosis rubra nasi is occasionally seen in half-caste and European children.

LICHEN PLANUS—LICHEN SPINULOSUS—PITYRIASIS RUBRA PILARIS—PARAKERATOSIS VARIEGATA—POROKERATOSIS.

Lichen planus is common in the tropics among Europeans and natives of the various races. In very dark-skinned natives the diagnosis may be difficult to the medical man used to seeing skin diseases in Europeans only. Apart from the colour, however, the skin lesions are identical, the papules having an angular outline and a flat, occasionally umbilicated, shiny surface. When the eruption disappears, it generally leaves behind some pigmentation, which is extremely well marked in natives. *Lichen nitidus* has been seen by us on the penis of a half-caste and several Europeans.

Lichen spinulosus is occasionally met with in children.

Of **Pityriasis rubra pilaris** we have seen a case of a European.

Parakeratosis variegata was seen by us in a half-caste patient. We have come across two cases among natives of Mibelli and Resphighi's **Porokeratosis.** We have seen a case of **Granuloma annulare** in a European planter and one in a native clerk.

TUMOURS OF THE SKIN.

The tumours met with in temperate zones are met with also in the tropics in Europeans as well as natives. There is no doubt, however, that native races are more subject to some classes of tumours than to others. We would call attention to the extreme frequency among the natives of cheloid, the common occurrence of fibroma molluscum, and the comparative rarity of epithelioma of the face.

CONNECTIVE-TISSUE TUMOURS.

Benign Connective-Tissue Tumours.

Simple fibroma, Fibroma pendulum, and **Fibroma molluscum** (neuro-fibromatosis of Recklinghausen) are very frequently met with in natives. **Myomata** are occasionally observed in our cases always on the face.

Angiomata are not rare, and **multiple Telangiectases** are fairly common, and **Lymphangiomata** very frequent.

Xanthoma planum and **Xanthoma tuberosum** are frequently observed.

Xanthoma diabeticorum is very common in India and Ceylon, where the better classes suffer greatly from diabetes. An example of Balzer's **Pseudo-Xanthoma** or **Elastorrhexis** affecting the abdomen was observed by us in a half-caste woman.

Cheloid.—This is extremely frequent in native races. According to some authors, negroes suffer from it sixteen to eighteen times as much as whites. In Indian races it is not so frequent as in African natives, but still, much more frequent than in

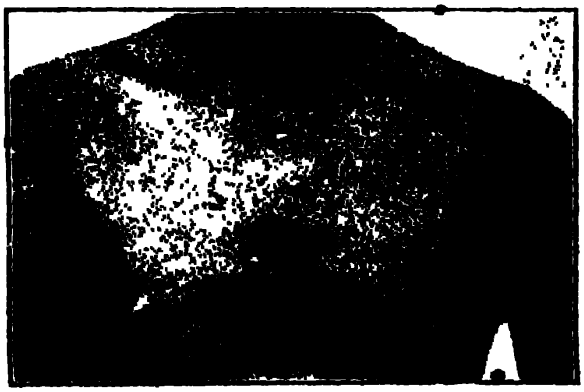

Fig. 097.—Cheloids.

Europeans. The smallest wounds, such as those made in tattooing, may be followed by cheloid. In Chinamen it often follows hypodermic injections of morphia.

Malignant Connective-Tissue Tumours.

Multiple sarcomatosis of the skin is rare. We have seen two cases, both in Sinhalese girls.

Mycosis fungoides has been observed by us once only in a half-caste man.

EPITHELIAL TUMOURS.

Benign Epithelial Tumours.

Epithelial moles are frequently observed.

Molluscum contagiosum is met with in all races.

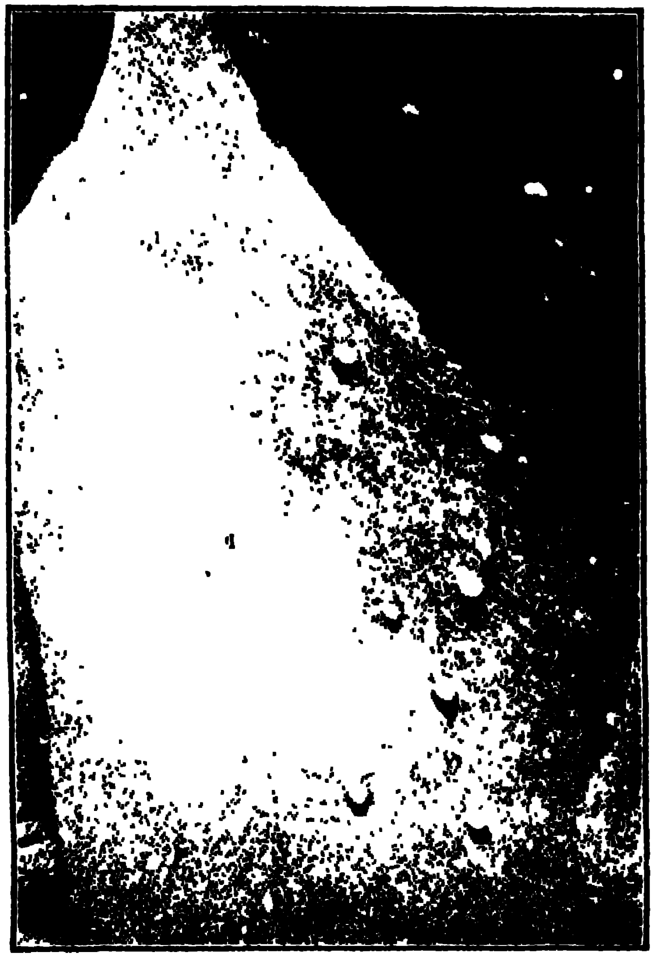

FIG. 898.—MOLLUSCUM CONTAGIOSUM.

Verrucæ and **Warts** are extremely common. In two instances we have seen Sinhalese boys covered all over the body with hundreds of warts. *Filiform warts* are met with, and *warts* on the genital organs

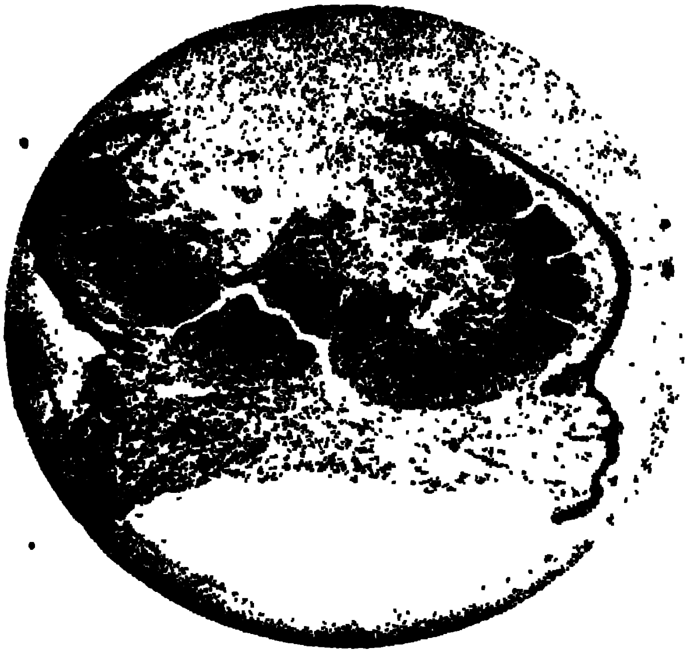

FIG. 899.—MOLLUSCUM CONTAGIOSUM: HISTOLOGICAL FEATURES.

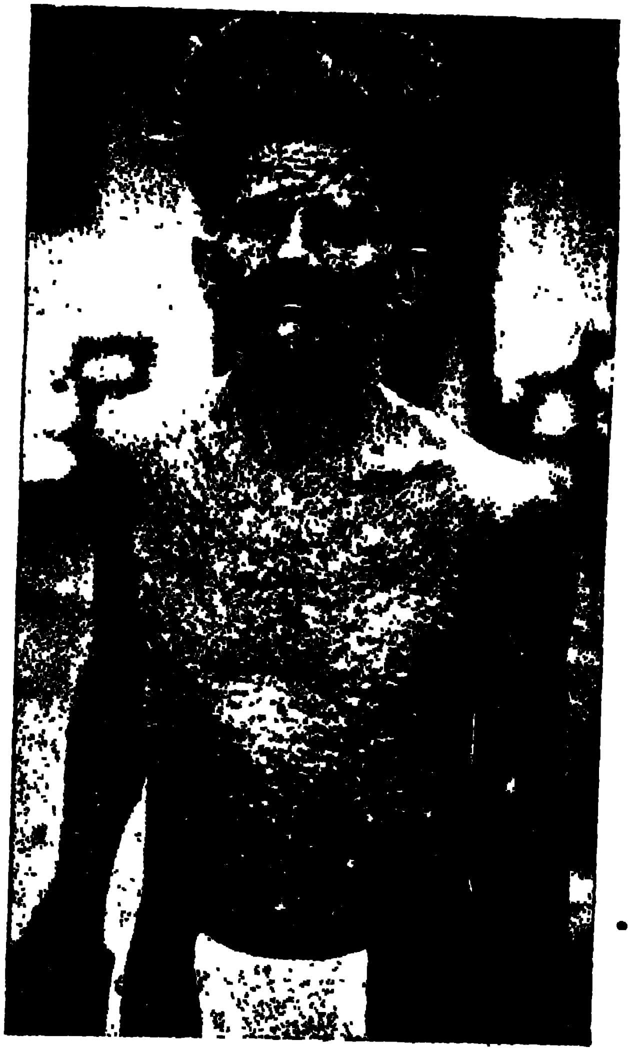

FIG. 900.—FIBROMA MOLLUSCUM IN A SINHALESE.

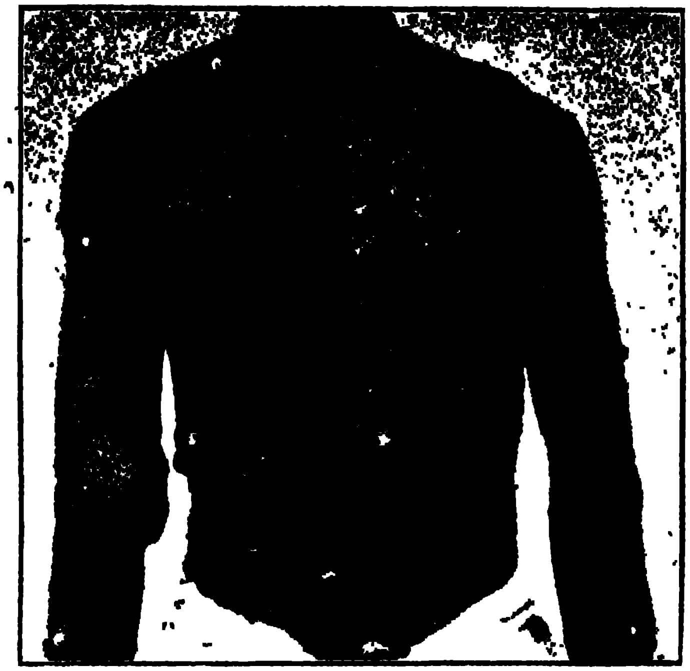

FIG. 901.—FIBROMA MOLLUSCUM: LARGER VARIETY.

FIG. 902.—FIBROMA MOLLUSCUM: LARGER VARIETY.

are very common. *Verruca senilis* and *Verruca seborrhaica* are frequent. The best treatment for ordinary warts is carbon dioxide snow.

Escomel has drawn attention to a peculiar treatment for warts in vogue among certain races in South America. These people apply the crushed body of a beetle belonging to the genus *Meloe* to the wart, the horny layer of which has been first scraped off. The wart disappears, leaving a slight whitish scar. The active principle is to be found in the beetle's blood.

Hyperkeratosis of the whole sole is often observed in natives going barefoot. We have seen several cases of *Cornu cutaneum*; the situation was generally on the hands, but in a case the condition developed at the edge of an ulcus tropicum (see Fig. 862, p. 2187).

Malignant Epithelial Tumours.

Rodent ulcer is comparatively rare among natives, but we have seen one case in a Sinhalese woman. We have observed a case of **Melanotic carcinoma** and two of **Paget's disease** of the nipple among half-castes.

MIXED TUMOURS.

Adenoma sebaceum of the face has been seen but rarely by us. We have never observed in the tropics cases of true **Angiokeratoma** on the hands, but we have seen a somewhat similar tumour on the scrotum of a European. A diffuse type of angiokeratoma of the foot somewhat resembling mycetoma has been described in South America (see p. 2147).

RHINOSCLEROMA.

A case of rhinoscleroma has been observed by us in an Indian coolie, and Gros has reported the occurrence of the disease in Algiers.

TUBERCULOSIS AND TUBERCULIDES—LUPUS ERYTHEMATOSUS.

Lupus vulgaris is met with in the tropics in all races, but, according to our observation, is far from being so common as in Europe.

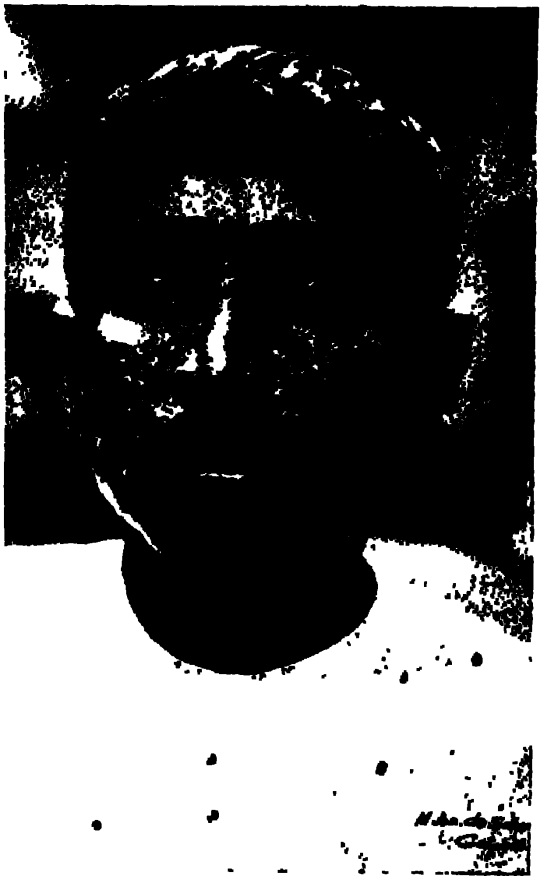

FIG. 903.—LUPUS VULGARIS IN A SINHALESE.

Tuberculosis verrucosa cutis is very rare, and **Scrofulodermia** much less common than in temperate zones. All the so-called tuberculides—**Lichen scrofulosorum, Acne scrofulosorum, Bazin's Erythema induratum, Folliclis,** and **Acnitis**—are observed but rarely in the tropics.

Lupus erythematosus, as regards which we agree with those writers who do not consider it of tubercular origin, is very rare in the tropics.

While tuberculosis of the lungs is at the present time extremely common in many parts of the tropics, skin affections of tubercular origin are, comparatively speaking, infrequently met with.

SYPHILIS—VENEREAL SORES—BALANO-POSTHITIS.

At the present date syphilis is rampant all over the tropics. In the past there is reason to believe that it was unknown in many of those tropical regions which were unopened to the cosmopolitan trade. According to Lambkin, in some parts of Uganda syphilis affects more than half of the population, and this enormous diffusion of the malady has taken place during recent years since the country

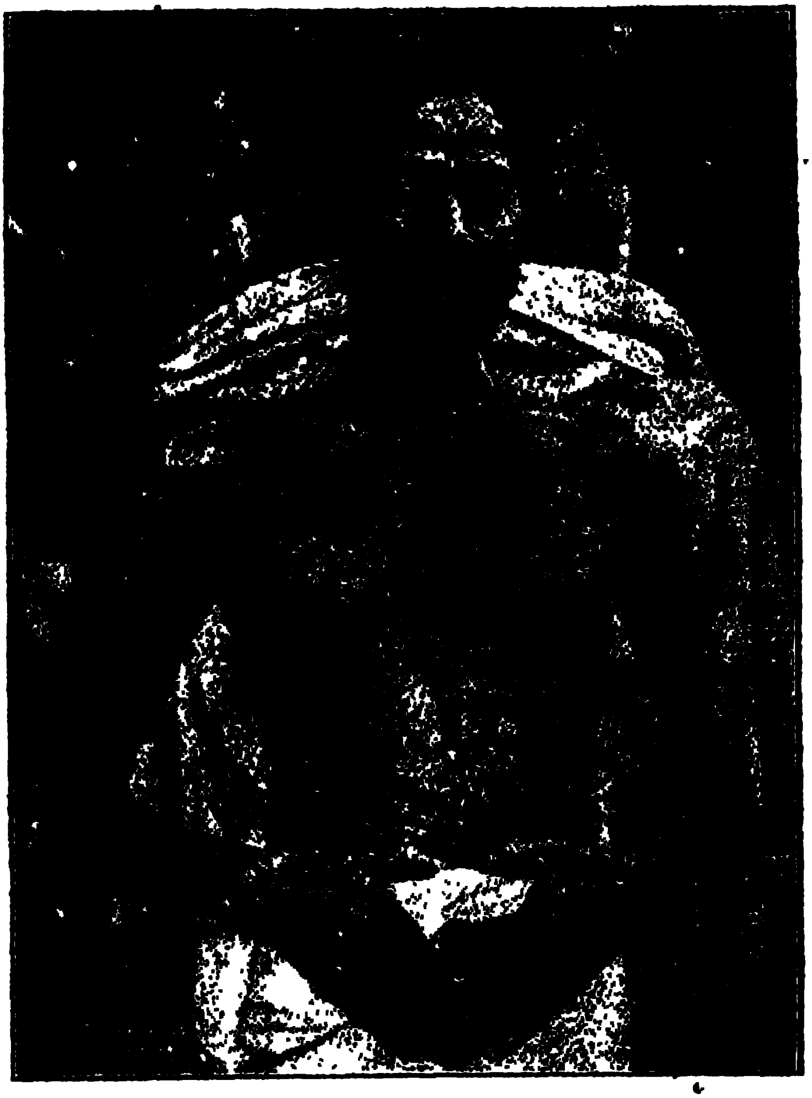

FIG. 904.—PAPULO-SQUAMOUS SYPHILIDE.

has been opened up. Syphilis is very frequently observed now also in all the other regions of Africa, and is very common in tropical Asia. It has been noted by Fox that in America it is much more frequent among negroes than among whites. In our experience, the virulence, as well as the symptoms of the disease, are not much different from what one sees in Europe. We can, however, confirm Brault's observation on the frequency of the primary sore on the supra-pubic region of natives, who regularly shave their pubis. Perhaps the general enlargement of the lymphatic glands is more marked in natives, and circinate and pustular syphilides, as observed by H. Fox, are more common. The tertiary ulcerative lesions are apt to become of enormous proportions, owing to secondary infections, and to the patient not seeking proper medical advice for a long time. Of great interest is the fact that in uncivilized native races the so-called parasyphilitic affections (progressive paralysis and tabes dorsalis) are extremely rare.

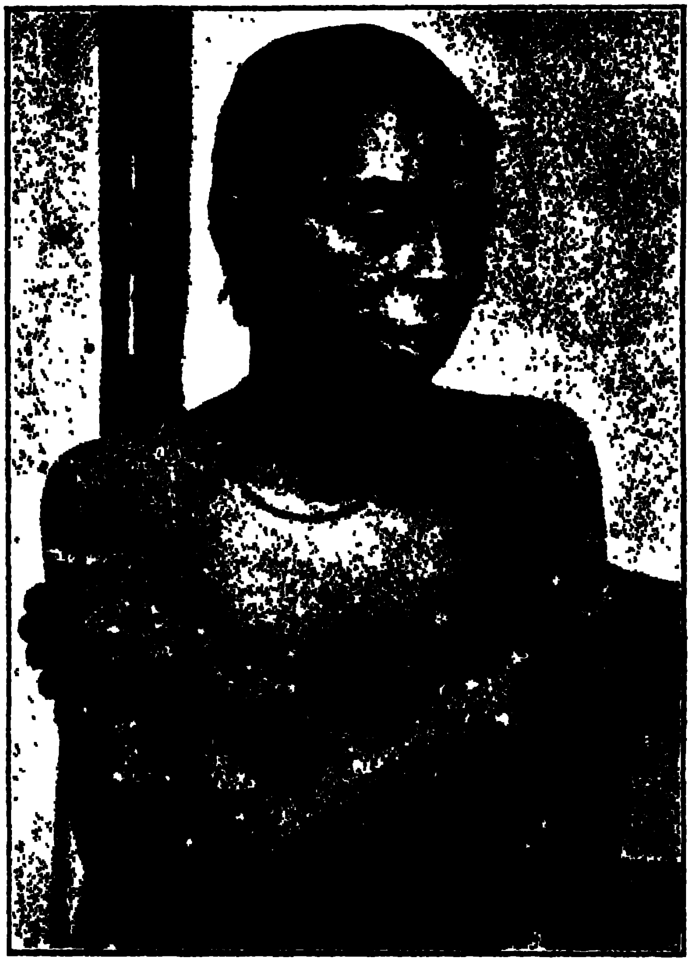

FIG. 985.—PUSTULAR SYPHILIDE

As regards the treatment of syphilis in the tropics, inunctions are very unpleasant in a hot damp climate. We generally prefer the ordinary internal treatment by hydrargyrum cum creta, gr. i., three times daily, and give also in most cases several injections of salvarsan or neosalvarsan. The technique of the salvarsan treatment has been given in the chapter on Frambœsia, p. 1560. We use also injections of various preparations of mercury. A mixed mercury and potassium iodide treatment is of advantage in some cases. Natives are said by some authors to be extremely susceptible to mercury, but in our experience this has been exaggerated. We generally give them the same doses as to Europeans. Native doctors give often mercury disguised in various ways. Decoctions of various herbs are also administered. In Abyssinia and Erythræa a decoction of a herb related to sarsaparilla and called 'usciva,' is much used, according to Annaratone.

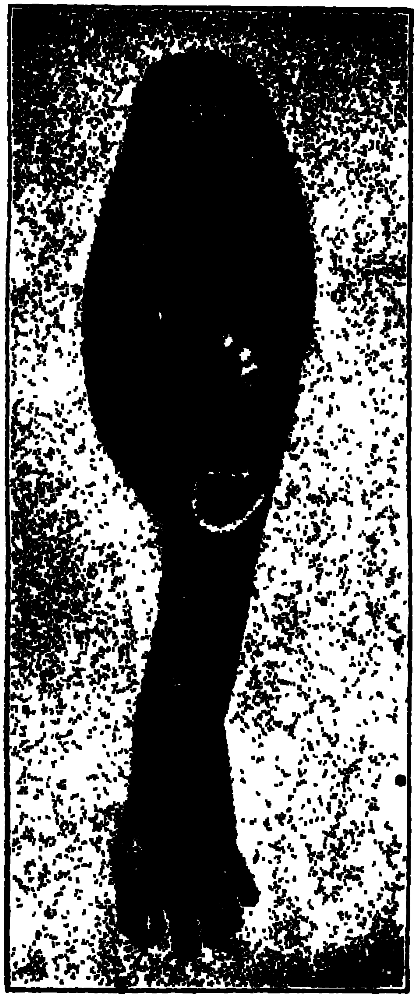

FIG. 906.—ULCER: TERTIARY SYPHILIS.

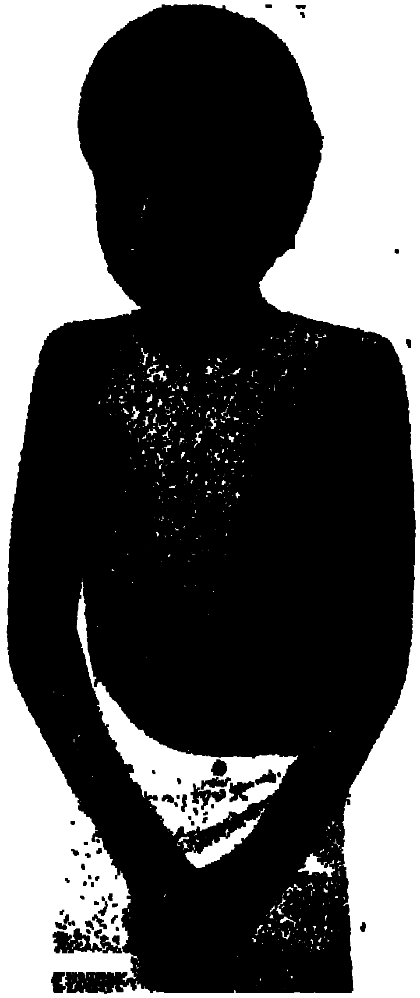

FIG. 907.—ICHTHYOSIS IN SINHALESE GIRL.

Venereal Sores.—These are common in all races, but are more apt to take a phagedænic character in the tropics.

Balano-posthitis.—Every type of balano-posthitis is met with in the tropics.

ICHTHYOSIS—SCLERODERMIA—MORPHEA.

Every type of **Ichthyosis** is met with in the tropics, from simple **Xerodermia** to **Ichthyosis hystrix.** Diffuse **Sclerodermia** is rare, but circumscribed sclerodermia (morphea) is rather frequent. We have seen a case of **Sclerema neonatorum** in a Sinhalese baby.

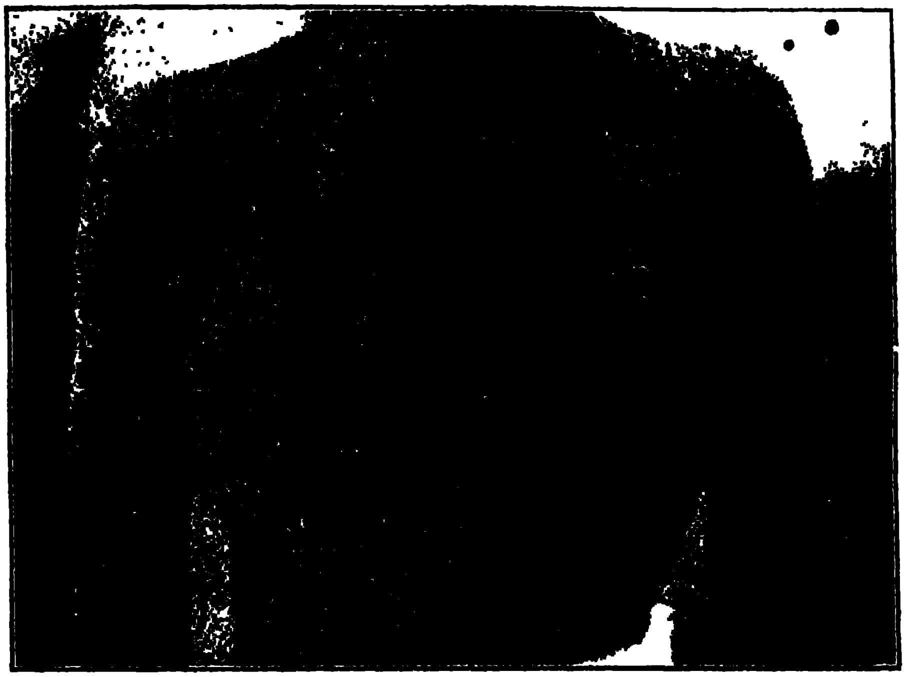

FIG. 908.—ICHTHYOSIS.

KAPOSI'S DISEASE—ACANTHOSIS NIGRICANS—DARIER'S DISEASE.

We have seen in the tropics several cases of **Kaposi's disease** (xeroderma pigmentosa) among European and half-caste children. We have come across in the tropics a case of **Acanthosis nigricans.** We have observed in Ceylon a typical case of Darier's disease in a Sinhalese beggar.

LENTIGO—CHLOASMA.

Freckling cannot be seen in very dark-skinned natives, but is easily visible in half-castes. It is very common among Europeans, especially those who live an open-air life, and are much exposed to the sun.

Chloasma is a very common affection in the tropics, and is found among Europeans as well as natives. The dark brownish or dirty yellowish patches of chloasma are plainly distinguishable in the skin of Indian and Sinhalese natives, though in African negroes they may be indistinguishable. (For more details see p. 2231.)

BIOTRIPSIS.

Cheatle has described under the name 'biotripsis,' or 'life-wear,' the trophic changes which take place in the skin of old people. In Europeans the skin, especially of the hands, may become at places shiny, smooth, inelastic, more or less pigmented than normal, and scar-like lesions may be present. Castellani has described a somewhat similar condition in old Sinhalese in whom the skin on the legs may present a peculiar appearance, becoming atrophic, and the superficial layers cracking. The condition, on superficial examination, might be taken for a mild type of ichthyosis. It is, however, probably a trophic condition due to old age. Chalmers and Drew have given an account of this condition as seen in the Sudan.

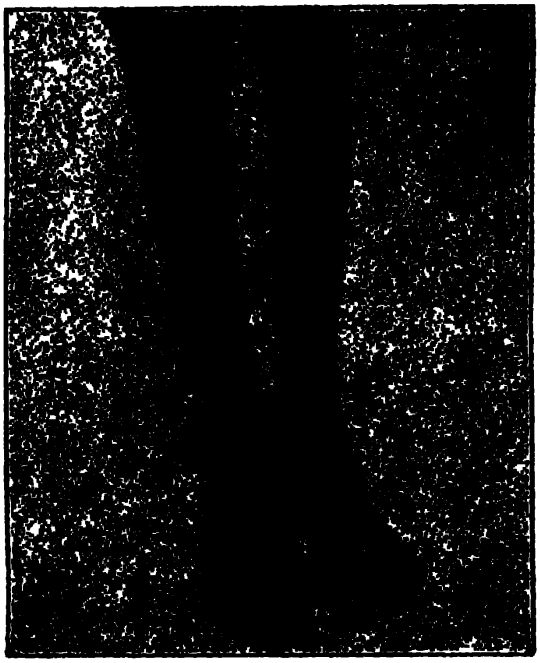

FIG. 909.—BIOTRIPSIS IN AN OLD SINHALESE MAN, SIMULATING A MILD TYPE OF ICHTHYOSIS.

DISEASES OF THE HAIR AND NAILS.

The diseases of parasitic origin are common, and have been described. Cases of **Hypertrichosis** in man and woman are occasionally met with. The so-called 'fragilitas crinium,' as well as **Trichorrhexis nodosa,** are rare in natives, this being probably due to the habit they have of frequently oiling and greasing the hair. We have seen cases of **Moniliform hair** (monilithrix) in Sinhalese and Tamils. In several Sinhalese decrepit old men, who wear their hair long, and do not take care of it, we have seen a condition of inextricable matting of the hair somewhat resembling **Plica.**

Canities is said to take place at a later age in negroes than in Europeans, but in our experience neither in negroes nor in Indian races is there any distinct difference. **Alopecia** of every origin is met with in the tropics. **Alopecia seborrhoeica** is very frequent among Europeans and educated natives. It is rare among the low classes and coolies. **Alopecia senilis** is less frequent in natives than in Europeans. **Alopecia areata** is apparently rare among natives, but recently we have come across several cases; it is fairly frequent among Europeans. We have seen a case of **pseudo-pelade** of Brocq (folliculitis decalvans) in a Sinhalese man.

All the diseases of the nails met with in temperate zones are found also in the tropics. **Brittle nails** (onychorrhexis), **ridged nails, transverse furrowing,** and **thinning of the nails, eggshell nails, shedding of the nails,** are conditions occasionally seen. **Leuconychia,** or whitening of the nails, either in spots (**leuconychia punctata**), linear (**leuconychia striata**), or affecting the whole nail (**leuconychia totalis**), is observed. We have described at p. 2236 a peculiar black pigmentation of the nails. **Onychia,** or inflammation of the nail matrix, is not rare. Ingrowing toenail is common. So-called **nail pterygium,** or outgrowth of the posterior nail fold, is occasionally seen, or the opposite condition, exposure of the root of the nail (**ficus unguium**), may be met with.

We have never observed a case of congenital atrophy, but we have seen one case of supernumerary nails. We have noted with comparative frequency a form of **onychogryphosis** affecting several members of the same family, and apparently hereditary to a certain extent. The nails are enormously thickened, and much longer than usual. All the nails may be affected, both those of the fingers and those of the toes.

Onychomycosis of various origin is a common affection, and has already been considered (p. 2059).

SOME COSMOPOLITAN DISEASES OF MUCOUS MEMBRANES.

Patches of **Leucoplakia** of the tongue are common in natives, and may be of various origin—syphilitic, framboetic, or due to irritation caused by smoking or chewing various substances. Cases of the so-called **circinate pityriasis linguæ** or **annulus migrans** are not rare. **Lingua nigra** is occasionally seen. We have already called attention to the *dark patches* found on the tongue in natives, and which by some writers have been described as a sign of ankylostomiasis. These pigmented patches are roundish or oval, and may be found also on the gums, the mucosa of the lips, on the soft and hard palate, and are apparently congenital. A condition which might be called **red or purple tongue,** and which often puzzles the newly arrived medical man, who does not know its origin, is extremely common in Ceylon among the coolies and lower-class natives, and is simply due to chewing betel. The pigmentation slowly disappears on the native discontinuing the use of betel. Cases of **furrowed tongue** (scrotal tongue) are not rare. We have seen a case of **Fordyce's disease** (pseudo-colloid of the lips) in a half-caste. A case of **cheilitis exfoliativa** in a European lady and cases of **perlèche** have been observed by us among European children. Under the term *seasonal recurrent ulceration of the lips*, Gros has described a very superficial ulceration on the lower lips in Algerian natives which is very common in the hot season, and is due, according to him, to a diplobacillus.
